ABSTRACT

Kilonovae, the ultraviolet/optical/infrared counterparts to binary neutron star mergers, are an exceptionally rare class of transients. Optical follow-up campaigns are plagued by contaminating transients, which may mimic kilonovae, but do not receive sufficient observations to measure the full photometric evolution. In this work, we present an analysis of the multi-wavelength dataset of supernova (SN) 2025ulz, a proposed kilonova candidate following the low-significance detection of gravitational waves originating from the potential binary neutron star merger S250818k. Despite an early rapid decline in brightness, our multi-wavelength observations of SN 2025ulz reveal that it is a type IIb supernova. As part of this analysis, we demonstrate the capabilities of a novel quantitative scoring algorithm to determine the likelihood that a transient candidate is a kilonova, based primarily on its 3D location and light curve evolution. We also apply our scoring algorithm to other transient candidates in the localization volume of S250818k and find that, at all times after the discovery of SN 2025ulz, there are ≥ 4 candidates with a score comparable to SN 2025ulz, indicating that the kilonova search may have benefited from the additional follow-up of other candidates. During future kilonova searches, this type of scoring algorithm will be useful to rule out contaminating transients in real time, optimizing the use of valuable telescope resources.

1. INTRODUCTION

The detection of gravitational waves (GWs) associated with the binary neutron star (BNS) merger GW170817 by the [LIGO/Virgo Collaboration \(2017\)](#), and the subsequent discovery of GW170817’s electromagnetic counterparts ([LIGO/Virgo Collaboration et al. 2017a](#)) GRB170817A ([V. Savchenko et al. 2017](#); [A. Goldstein et al. 2017](#)) and AT2017gfo ([I. Arcavi et al. 2017a](#); [D. A. Coulter et al. 2017](#); [V. M. Lipunov et al. 2017](#); [S. J. Smartt et al. 2017](#); [M. Soares-Santos et al. 2017](#); [N. R. Tanvir et al. 2017](#); [S. Valenti et al. 2017](#)), opened a powerful new window on our Universe. The unambiguous association of the short gamma-ray burst (SGRB) GRB170817A and kilonova (KN) AT2017gfo ([LIGO/Virgo Collaboration et al. 2017a](#)) provided unique insights into the relativistic engine driving SGRBs ([LIGO/Virgo Collaboration et al. 2017b](#); [R. Margutti et al. 2017](#); [K. D. Alexander et al. 2017](#); [W. Fong et al. 2017](#); [V. Savchenko et al. 2017](#); [A. Murguia-Berthier et al. 2021](#)), the properties of neutron stars (*e.g.*, their equation of state; [LIGO/Virgo Collaboration 2018](#); [D. Radice et al. 2018](#)), and the formation of *r*-process elements in the ejecta of BNS mergers ([I. Arcavi et al. 2017a](#); [P. S. Cowperthwaite et al. 2017](#); [N. R. Tanvir et al. 2017](#); [M. R. Drout et al. 2017](#); [M. M. Kasliwal et al. 2017](#); [C. D. Kilpatrick et al. 2017](#); [S. J. Smartt et al. 2017](#)).

Theoretical models (*e.g.*, [D. Kasen et al. 2015, 2017](#); [B. D. Metzger 2017](#); [B. D. Metzger et al. 2024](#); [Y.-X. Chen & B. D. Metzger 2025](#)), combined with observations of AT2017gfo, demonstrate that photometric observations can typically discriminate between KNe and other transient types. After a BNS merger occurs, *r*-process nucleosynthesis in the neutron-rich ejecta forms heavy *r*-process elements, including lanthanides and actinides ([B. D. Metzger et al. 2010](#)). The radioactive decay of the heavy elements heats the ejecta, resulting in a faint and rapidly fading (few days to a week) transient whose spectral energy distribution (SED) primarily peaks in the near-infrared ([L.-X. Li & B. Paczyński 1998](#); [J. Barnes & D. Kasen 2013](#); [M. Tanaka & K. Hotokezaka 2013](#); [B. D. Metzger 2017](#)). If the merger remnant launches outflows, it may (primarily depending on the neutron mass in the ejecta) inject energy and result in a re-brightening of the light curve in the infrared, while only resulting in a “plateau” in the optical ([D. Kasen et al. 2015](#)).

Beyond GW170817, searches for an electromagnetic counterpart associated with a GW signal have been unsuccessful ([I. Andreoni et al. 2019](#); [M. W. Coughlin et al. 2019](#); [D. Dobie et al. 2019](#); [D. A. Goldstein et al. 2019](#); [S. Gomez et al. 2019](#); [G. Hosseinzadeh et al. 2019](#); [M. J. Lundquist et al. 2019a](#); [I. Andreoni et al. 2020](#); [S. Antier et al. 2020a,b](#); [K. Ackley et al. 2020](#); [A. Garcia et al. 2020](#); [B. P. Gompertz et al. 2020](#); [M. M. Kasliwal et al. 2020](#); [R. Morgan et al. 2020](#); [A. S. Pozanenko et al. 2020](#); [A. L. Thakur et al. 2020](#); [N. Vieira et al. 2020](#); [A. M.](#)

Watson et al. 2020; S. Anand et al. 2021; K. D. Alexander et al. 2021; R. L. Becerra et al. 2021; D. Bhakta et al. 2021; S.-W. Chang et al. 2021; S. de Wet et al. 2021; S. Dichiara et al. 2021; D. Dobie et al. 2021; C. D. Kilpatrick et al. 2021; S. R. Oates et al. 2021; T. Ohgami et al. 2021; K. Paterson et al. 2021a; D. L. Tucker et al. 2022; O. R. McBrien et al. 2021; T. de Jaeger et al. 2022; J. C. Rastinejad et al. 2022; T. Ahumada et al. 2024; M. Pillas et al. 2025; L. Hu et al. 2025; D. Frostig et al. 2025; T. Ahumada et al. 2025; G. S. H. Paek et al. 2025; P. Darc et al. 2025; J. H. Gillanders et al. 2025). During these searches, there are often many transients that are spatially and temporally co-located with a given GW event, a subset of which are new, extragalactic events. Some of these contaminants are impostors, which have light curves that are initially faint and rapidly declining, appearing similar to a KN for several days, but eventually evolving away from expectations (O. R. McBrien et al. 2021; T. Barna et al. 2025). Quickly ruling out interloping transients in real time will help the community focus their follow-up efforts on more promising candidates.

Due to their initial rapid decline, type IIb supernovae (SNe IIb) are common KN impostors (T. Barna et al. 2025). SNe IIb are characterized by weak hydrogen absorption lines at early times ($\sim$ weeks to months after explosion) and likely originate from a progenitor star with a partially stripped hydrogen envelope (P. Podsiadlowski et al. 1993; S. E. Woosley et al. 1994; M. W. Richmond et al. 1994; T. Matheson et al. 2000; A. Elmhamdi et al. 2006; R. A. Chevalier & A. M. Soderberg 2010). Importantly, SNe IIb can feature a double-peaked light curve in the ultraviolet, optical, and infrared (*e.g.*, K. Matthews et al. 2002). The first peak ($\sim$ few days after explosion) is dominated by shock breakout and subsequent cooling (M. W. Richmond et al. 1994; I. Arcavi et al. 2017b; K. K. Das et al. 2023). The initial shock cooling lasts ~ 5 –7 days, after which the radioactive decay of ^{56}Ni heats the ejecta and dominates the observed emission, powering the second peak (*e.g.*, P. J. Benson et al. 1994). In addition to their initial rapid decline, this re-brightening may appear similar to the “plateau” phase of a KN light curve. But, conventional KN models are unable to reproduce a significant re-brightening in the optical for more than a few days (D. Kasen et al. 2015, 2017).

In this paper, we focus on electromagnetic candidates potentially associated with the sub-threshold GW event S250818k, a GW event with a 29% probability of being a BNS merger and a 71% probability of being of terrestrial origin (LVK Collaboration 2025a; LVK Collaboration 2025b). In particular, we present our observations of

SN 2025ulz³⁰, including new observational evidence that SN 2025ulz is a type IIb SN and not a KN counterpart to S250818k. We find that both the photometric evolution and spectrum are consistent with other SNe IIb and inconsistent with both AT 2017gfo and a suite of KNe models.

We also present a novel algorithm for quantifying the likelihood that a specific electromagnetic counterpart is associated with a BNS or Neutron Star–Black Hole (NSBH) GW event. We apply this algorithm to SN 2025ulz and the 120 other transients discovered (1) within one week of the putative merger and (2) within the 95% localization region of S250818k. We find ~ 1 –2 candidates have a photometric evolution roughly consistent with a KN. But, these ~ 2 candidates only have 2–5 publicly available photometry points, making it unclear if any of them are true KNe. Through this analysis, we demonstrate the current capabilities of this quantitative scoring algorithm. In the future, we will continue development of this algorithm and make it available as part of a publicly available web application.

The paper is organized as follows. Section 2 describes the discovery and initial public observations of S250818k and SN 2025ulz. Section 3 provides the details of our follow-up observations, spanning ultraviolet to radio wavelengths. In Section 4, we analyze our observations and discuss the implications for the interpretation of SN 2025ulz as an SN IIb. In Section 5 we describe our search for additional KN candidates associated with S250818k. Finally, we summarize and conclude in Section 6. Throughout this work we assume a flat Λ CDM cosmology with $H_0 = 69.6 \text{ km s}^{-1} \text{ Mpc}^{-1}$ (W. L. Freedman et al. 2020).

2. DISCOVERY OF S250818k AND SN 2025ulz

The GW event S250818k was initially discovered by the LIGO/Virgo/KAGRA (LVK) Collaboration as a sub-threshold event detected at 2025-08-18 01:20:19 UTC (GPS time: 1439515224.03) and reported at 2025-08-18 01:20:35 UTC. Preliminary classification of the event from the pycbc pipeline yielded a 29% probability of being a BNS merger and a 71% probability of being a Terrestrial event (LIGO Scientific Collaboration et al. 2025a). This initial classification also yielded a 50th (90th) percentile confidence sky localization that spanned 205 deg^2 (786 deg^2) with a posterior luminosity distance of $259 \pm 62 \text{ Mpc}$. S250818k has a false alarm rate, also estimated by the pycbc online analysis

³⁰ We consistently refer to the transient as “SN 2025ulz”, rather than “AT 2025ulz”, since this is the official IAU name on the Transient Name Server.

Figure 1. The IGWN (International Gravitational Wave Network) skymap credibility contours (orange: 50%, white: 90%) of S250818k, and the locations of all 121 candidates we found within the 95% credibility region from the Transient Name Server (TNS). The color of the point represents the overall score from our vetting, which is described in [section 5](#).

Table 1. SN 2025ulz Properties

Property	Value	Source
RA	15h51m54.201s	R. Stein (2025)
Dec	+30d54m08.67s	R. Stein (2025)
Redshift	0.0848	V. Karambelkar et al. (2025)
$E(B-V)_{MW}$	0.0243 mag	D. J. Schlegel et al. (1998) ; E. F. Schlafly & D. P. Finkbeiner (2011)
Host SFR	$\sim 1 M_{\odot} \text{ yr}^{-1}$	D. O. Jones et al. (2024) ; This work (subsection 4.4)
Envelope Mass (RSG)	$0.027^{+0.009}_{-0.007} M_{\odot}$	This work (subsection 4.2)
Progenitor Radius (RSG)	$0.6^{+1.6}_{-0.4} \times 10^{13} \text{ cm}$	This work (subsection 4.2)
Envelope Mass (BSG)	$0.14^{+0.08}_{-0.04} M_{\odot}$	This work (subsection 4.2)
Progenitor Radius (BSG)	$0.5^{+2.0}_{-0.3} \times 10^{13} \text{ cm}$	This work (subsection 4.2)

pipeline ([S. A. Usman et al. 2016](#)), of $6.81 \times 10^{-8} \text{ Hz}$ (1 per 170 days), close to the reported LVK threshold for significant events after accounting for the trials factor³¹ (e.g., see [S. S. Chaudhary et al. 2024](#), for a full description of these parameters). We note that the probability that the system had a neutron star (HasNS)

and the probability that the system ejected a non-zero amount of neutron star matter (HasRemnant) were both estimated to be 1.0, under the assumption that the event was non-terrestrial.

The revised S250818k event analysis (*i.e.*, the “initial” analysis), provided on 2025-08-20 04:52:51 UTC (~ 48 hours after the first alert), and the S250818k “update” analysis, provided on 2025-08-20 09:57:08 UTC, changed these parameters slightly (see, *e.g.*, [LVK Collaboration 2025a](#); [LVK Collaboration 2025b](#)). Given the short gap

³¹ See description in <https://emfollow.docs.ligo.org/userguide/analysis/index.html#alert-threshold-trial-factor>.

between these updates, we provide only the latter here, which we use for the majority of our analysis. The final event classification changed only marginally and remained consistent with a 29% probability of being a BNS merger and 71% probability of being Terrestrial. Similarly, the false alarm rate remained at 6.81×10^{-8} Hz. The final Bilby offline analysis map expanded the localization slightly to a 50th (90th) percentile sky localization of 276 deg^2 (949 deg^2) with a corresponding all-sky distance constraint of $237 \pm 62 \text{ Mpc}$ (Figure 1). Finally, we note that the Bilby analysis revised the `HasNS` and `HasRemnant` estimates down to 0.8 each, while the chirp mass estimate placed $>99\%$ of the probability within the $(0.1, 0.87) M_{\odot}$ bin.

On 2025 August 18 17:01:30 UTC, ~ 16 hours after the initial GW alert, R. Stein et al. (2025) reported the discovery of a potential electromagnetic counterpart to S250818k: SN 2025ulz. Following this at ~ 2.6 days after the discovery of S250818k, V. Karambelkar et al. (2025) reported that the most likely host galaxy of SN 2025ulz has a spectroscopic redshift $z = 0.0848$ ($D \approx 360 \text{ Mpc}$). This distance is somewhat consistent with the distance to S250818k along the line of sight to SN 2025ulz, with a $\approx 68\%$ joint probability of the transient and GW distance distributions (see subsections 5.2 & 5.6). This motivated a global follow-up campaign with facilities covering the X-ray through radio wavelengths (e.g., J. H. Gillanders et al. 2025, in the optical). Subsequent messages posted on the General Coordinates Network (GCN) over the next ~ 3 days reported photometry consistent with a fast-fading red transient with a similar decay rate to AT 2017gfo (X. J. Hall et al. 2025), but ~ 1.5 orders of magnitude more luminous. The source was never detected in the X-ray (X. J. Hall et al. 2025; M. Nakajima et al. 2025; R. L. Becerra et al. 2025a; R. Z. Li et al. 2025). A source was detected in the radio by the MeerKAT telescope (G. Bruni et al. 2025a,b) but this emission was diffuse and later shown to likely be associated with the host galaxy (L. Rhodes et al. 2025; G. Bruni et al. 2025c). The source was not detected with any other radio telescope (R. Ricci et al. 2025b,d; G. Bruni et al. 2025d). The basic properties of SN 2025ulz are summarized in Table 1.

On 2025-08-23 15:18:41 UTC, ~ 5 days after the discovery of S250818k, J. Freeburn et al. (2025) reported a re-brightening in the i -band light curve of SN 2025ulz, and subsequent GCNs confirmed this finding (C. Angulo et al. 2025; J. H. Gillanders et al. 2025a; R. L. Becerra et al. 2025c), making the light curve more consistent with a SN I Ib rather than AT 2017gfo or other plausible KN emission. Soon after, a new spectrum confirmed the presence of a broad ($v \sim 15,600 \text{ km s}^{-1}$) P-Cygni

H α line, consistent with other SNI Ib at this phase (S. Banerjee et al. 2025). Despite this, SN 2025ulz continued to be observed and the exact origin remains hotly debated (e.g., M. M. Kasliwal et al. 2025; J. H. Gillanders et al. 2025). J. H. Gillanders et al. (2025) searched the S250818k localization region with Pan-STARRS and found no promising candidate KNe, concluding that SN 2025ulz is qualitatively consistent with a SN classification and incompatible with KN models.

3. MULTIWAVELENGTH FOLLOW-UP OBSERVATIONS OF SN 2025ulz

Given the strong temporal and spatial association of SN 2025ulz with S250818k, we observed it from the ultraviolet to radio wavelengths. In the following subsections we describe these previously unreported observations. All optical photometry and spectra will be made public on WISerEP (O. Yaron & A. Gal-Yam 2012), and the radio observations and optical photometry will be made public, jointly, on the Open multiwavelength Transient Event Repository (N. Franz et al. 2025, OTTER). All photometry is also provided in Appendix C.

3.1. Public Photometry

We gather the publicly available data reported on the GCN and the TNS for SN 2025ulz. This includes the ultraviolet, optical, infrared, and radio observations reported in GCN circulars (with the exception of the MeerKAT data, which we reanalyze ourselves; Section 3.4). We also include the photometry from J. H. Gillanders et al. (2025).

Using the methodology described in G. Hosseinzadeh et al. (2024), we also query the Asteroid Terrestrial-impact Last Alert System (ATLAS; J. L. Tonry et al. 2018) forced photometry server (K. W. Smith et al. 2020; L. Shingles et al. 2021) at the coordinates of SN 2025ulz from ~ 180 days prior to ~ 20 days after it was discovered. ATLAS forced photometry subtractions are based on difference images, and are subject to false detections attributed to bad subtractions, potentially due to artifacts in template images. Therefore, for SN 2025ulz, we consider an ATLAS forced photometry observation to be a detection if it (1) is significant at the 5σ level and (2) has at least 2 other 5σ detections within a 10-day window.

3.2. Optical Photometry

The site of SN 2025ulz was observed over multiple epochs with the *Hubble Space Telescope* (HST) using the Wide Field Camera 3 (WFC3) as part of GO-17450 and GO-17805 (PI: Troja). The counterpart and its host galaxy were imaged in the F336W, F606W, F110W, and

Figure 2. A false color image of the HST WFC3 observations of SN 2025ulz. We include the F606W image from 26 Aug (blue; $\delta t \sim 8$ days), the F110W image from 27 Aug (green; $\delta t \sim 9$ days), and the F160W image from 28 Aug 2025 (red; $\delta t \sim 10$ days). We highlight the position of SN 2025ulz showing its close in projection to the core of its host galaxy.

F160W bands from 22–28 August 2025. We downloaded all *HST* images of SN 2025ulz from the Mikulski Archive for Space Telescopes (MAST) and processed them with `hst123` (see C. D. Kilpatrick 2021; C. D. Kilpatrick et al. 2021), including frame-to-frame alignment with `Tweakreg` and image co-addition with `astrodrizzle` (STSCI Development Team 2012), and photometry in the calibrated image frames with `dolphot` (A. Dolphin 2016). We obtain detections of SN 2025ulz in every epoch and band, and we provide the corresponding photometry in Table 4 (Appendix C). A false color image of a subset of the *HST* imaging from 26–28 August 2025 in the F606W, F110W, and F160W bands is in Figure 2.

We observed SN 2025ulz in *ri*-bands on 22 August 2025 and *iz*-bands on 30 August 2025 using the imaging mode of the Binospec instrument (D. Fabricant et al. 2019) on the 6.5-m MMT telescope located on Mt. Hopkins in Arizona, USA. We processed all imaging using the POTPyRI pipeline³² (see, *e.g.*, Y. Dong et al. 2024;

CHIME/FRB Collaboration et al. 2025). We calibrate photometric zeropoints using stars in the Panoramic Survey Telescope and Rapid Response System (Pan-STARRS; K. C. Chambers et al. 2016) data release (DR) 1 photometric survey. We derive an effective point spread function (ePSF) model for each processed image by fitting bright, isolated stars with the `EPSFBuilder` tool from the `photutils` package in `Astropy`. We then perform PSF-fitting at the location of SN 2025ulz, as well as a set of 20 or more stars spread throughout the image. A first-order two-dimensional polynomial is included in the PSF fitting to account for any spatially varying background and to avoid over-fitting of the stars. To estimate the uncertainty of each flux measurement, we set the statistical uncertainty per pixel using the RMS error of the fit residuals scaled by a factor of the square root of the reduced χ^2 . We then multiply this value by the number of ‘noise pixels’ of the ePSF³³. We use the set of Pan-STARRS calibration stars to derive aperture corrections ($\lesssim 0.1$ mag in all filters) to scale PSF-fitting magnitudes to the images’ photometric zeropoints. For the total uncertainty in our reported magnitudes, we report the statistical flux uncertainty summed in quadrature with the RMS error of the stars used in the zeropoint and ePSF aperture correction. Despite the large FOV of Binospec, the limited number of isolated stars in the Pan-STARRS catalog results in the zeropoint RMS dominating the reported error. For photometry taken on 22 August 2025, we report 5σ limits. The limiting magnitude is calculated by placing 50 random background apertures within 70 pixels from the target position and taking the standard deviation of the aperture values. We then repeat this ten times and choose σ to be the average of the ten runs. Finally, we convert the 5σ flux in counts to magnitude using the photometric zeropoint derived from the calibration stars.

We observed SN 2025ulz on 28 August 2025 with the Goodman High-throughput Spectrograph (J. C. Clemens et al. 2004) in imaging mode on the Southern Astrophysical Research Telescope (SOAR) on Cerro Pachon, Chile. We used *riz* bands with a single 100 s frame and 3×200 s images in each band. All SOAR/Goodman imaging data were processed using `photpipe` (A. Rest et al. 2005) using methods described in J. C. Rastinejad et al. (2025). We calibrated all data using bias and dome flat-field frames obtained on the same night and instrumental configuration and aligned to the *Gaia* DR3 astrometric frame (Gaia Collaboration et al. 2023a) us-

³² <https://github.com/CIERA-Transients/POTPyRI>

Figure 3. *Top:* A comparison of the *gri* light curves for SN 2025ulz (black), SN 2016gkg (blue; [L. Tartaglia et al. 2017](#)), SN 2022hnt (orange; [J. R. Farah et al. 2025](#)), and AT2017gfo (red; [V. A. Villar et al. 2017](#)). For SN 2025ulz, We choose an explosion date of MJD=60904 based on our shock cooling modeling (see [subsection 4.2](#)). The best fit (*i.e.*, lowest sum of the residual squared) *r*-band KN model (from [D. Kasen et al. 2017](#)) to SN 2025ulz for the early time ($\delta t \leq 6$ days) light curve decline is shown as a solid line. We also show the *r*- (black dashed line) and *g*-band (black dotted line) models for SN 2016gkg from [A. L. Piro et al. \(2017\)](#). At phase $\delta t \lesssim 6$ days all four observed light curves appear to redden as they fade rapidly at around the same rate. At $\delta t \gtrsim 6$ days, the light curves of SN 2025ulz and the other SNe I Ib begin to re-brighten while the KN light curve continues to fade rapidly. *Bottom:* The *g-r* color evolution of SN 2025ulz as compared to AT 2017gfo, SN 2016gkg, SN 2022hnt, and 7 other SNe I Ib (SN 1993J, [M. W. Richmond et al. 1994](#); SN 2008ax, [A. Pastorello et al. 2008](#); SN 2011dh, [I. Arcavi et al. 2011](#); SN 2011ei, [D. Milisavljevic et al. 2013](#); SN 2011fu, [A. Morales-Garoffolo et al. 2015](#); SN 2013df, [A. Morales-Garoffolo et al. 2014](#); SN 2024uwq, [B. M. Subrayan et al. 2025](#)). The color evolution of SN 2025ulz is very similar to the rest of the SNe I Ib population.

ing point-like astrometric standards. We then performed PSF photometry in each frame using a custom version of *dophot* ([P. L. Schechter et al. 1993](#)) and calibrated the photometry using Pan-STARRS DR2 *riz* photometric standards in each image ([H. A. Flewelling et al. 2020](#)). We then resampled each image to a common, undistorted astrometric frame and stacked images in each band with *Swarp* ([E. Bertin 2010](#)). SN 2025ulz is located close to the nucleus of its host galaxy, and so we subtracted Pan-STARRS 3π images in each band using *hotpants* ([A. Becker 2015](#)). We detect a faint residual in *i*-band in the subtracted images and we place 3σ upper limits on the presence of a counterpart in *r* and *z* bands using forced aperture photometry within $2.5\times$ the full-width at half maximum (FWHM) of the difference image PSF and at the location of SN 2025ulz.

We observed SN 2025ulz over multiple epochs starting on 21 August 2025 with the T80N-Cam on the Observa-

torio Astrofísico de Javalambre (OAJ) 83 cm telescope located at the Astrophysical Observatory in Teruel, Spain. We observed in *r* and *i*-bands with 2×300 s in *r*-band and 4×300 s in *i*-band. All imaging was processed following the same procedures as with the SOAR imaging, including Pan-STARRS subtractions, using the S-PLUS Transient Extension Program (STEP) pipeline, as described in [A. Santos et al. \(2024\)](#). We report detections and 3σ upper limits on our T80S observations using a methodology similar to our SOAR imaging.

The *gri* light curve of SN 2025ulz is shown in [Figure 3](#), with both our photometry and publicly available photometry. Our other observations are used for modeling and provided in [Table 4](#).

3.3. Optical Spectra

We observed SN 2025ulz and its host galaxy SDSS J155154.16+305409.3 starting on 21 August 2025

Figure 4. Comparison of the MMT optical spectrum of SN 2025ulz (black) to the type IIb SN 2022hnt (orange; J. R. Farah et al. 2025), SN 2016gkg (sky blue; L. Tartaglia et al. 2017) and the kilonova AT 2017gfo (red; E. Pian et al. 2017), all at similar phases. The low opacity colored regions behind the spectra show the 1-sigma uncertainty and the grey vertical strips are regions of telluric features. The spectral features from SN 2025ulz appear most similar to SN 2022hnt and do not show any similarity with AT 2017gfo. Most notably, the broad P-Cygni $H\alpha$ feature highlighted in dark blue, present in both SN 2025ulz and SN 2022hnt, is not expected, nor seen, in the KN spectrum.

with the Low-Resolution Imaging Spectrograph (LRIS; J. B. Oke et al. 1995) on the Keck-I telescope located on Maunakea, Hawaii, USA. We observed with the 400/3400 grism on the blue side and 400/8500 grating on the red side in conjunction with the d560 dichroic and the $1.0''$ long slit, covering a continuous wavelength range of approximately 3000–10500 Å. In this mode, we observed for 5×930 s and 5×900 s on the blue and red arms, respectively, although we cut the final blue exposure to 628 s and red exposure to 646.6 s due to poor atmospheric transparency. We processed all spectra using PyPeIt (J. X. Prochaska et al. 2020a,b), calibrating the science spectra with dome flat exposures and obtaining a wavelength solution with arc lamp exposures obtained on the same night and instrumental configuration. We extracted a one-dimensional spectrum located around the position of the host galaxy and performed flux calibration with a spectrum of BD+33d2642 obtained on the same night, with telluric corrections derived from atmospheric grids of Maunakea. We then scale the continuum flux to the Pan-STARRS photometry, which scales the line flux appropriately.

Additionally, we observed SN 2025ulz on 30 August 2025 ($\delta t \sim 12$ days post-discovery) using Binospec on MMT. This spectrum was taken with an exposure time of 5×900 s using a $1.0''$ slit and the 270 lines/mm grating centered at 6800 Å for a total wavelength range of roughly 3800–9200 Å. This spectrum was triggered using the PyMMT package (M. Shrestha et al. 2024) as part of the Searches After Gravitational waves Using Arizona Observatories program (SAGUARO; M. J. Lundquist et al. 2019b; K. Paterson et al. 2021b; J. C. Rastinejad et al. 2022; G. Hosseinzadeh et al. 2024). Processing of the 2D Binospec spectrum, including flat-fielding, sky subtraction, and wavelength and flux calibration, were done using the Binospec IDL pipeline (J. Kinsky et al. 2019). The 1D spectrum was then extracted using standard IRAF techniques (D. Tody 1986, 1993). A careful telluric correction was performed using the IRAF `telluric`³⁴ task, by creating an atmospheric model using the standard star (G191-B2B). We removed the in-

³⁴ <https://iraf.readthedocs.io/en/doc-autoupdate/tasks/noao/imred/specred/telluric.html>

intrinsic stellar features from the standard and the resulting telluric model was scaled, wavelength-shifted and divided to get the telluric corrected science spectrum (N. Rudolf et al. 2016). The reduced Binospec spectrum is shown in Figure 4, alongside similar phase spectra of the type IIb SN 2022hnt (J. R. Farah et al. 2025), SN 2016gkg (L. Tartaglia et al. 2017), and the kilonova AT 2017gfo (E. Pian et al. 2017).

3.4. Radio Observations

On 26 August 2025, we observed SN 2025ulz with the upgraded Giant Metrewave Radio Telescope (uGMRT) under program 48.120 (PI: Laskar). Observations were taken using the band 5 receiver ($\nu \approx 1.26$ GHz) with a total observation length of 106 minutes. We used 3C286 and J1609+266 as the flux and phase calibrators, respectively. The data were reduced and imaged using standard practices in the Common Astronomy Software Applications version 6.5.4 (CASA v6.5.4; J. P. McMullin et al. 2007; CASA Team et al. 2022), including two rounds of self-calibration. This observation had a beam size of $\sim 2.5''$ and a root mean square (RMS) error of $\sim 27 \mu\text{Jy}$, and no evidence of emission at the location of SN 2025ulz.

We observed SN 2025ulz with the Very Large Array (VLA) over 2 epochs on 22 and 30 August 2025 (VLA configuration B→C) under program 22A-417 (PI: Alexander). The first epoch spanned 1 hour and was at C-band ($\nu \approx 6$ GHz). In the first epoch 3C48 and J1602+3326 were used as the flux and phase calibrators, respectively. The second epoch spanned 2 hours and was at S-, C-, and X-bands ($\nu \approx 3, 6, 10$ GHz, respectively). During the second epoch, 3C286 and J1602+3326 were used as the flux and phase calibrators respectively. All data were reduced and imaged using standard practices in CASA v6.5.4. All epochs had a beam size of $\sim 0.5'' - 1.5''$ and the image RMS was $\sim (6 - 10) \mu\text{Jy}$, with no evidence of emission.

SN 2025ulz was observed for three epochs using shared time on the South African MeerKAT radio telescope from programs MKT-24113/MKT-24127/MKT-24270 (PI: Bruni/Alexander/Mooley; triggered by PI Bruni under MKT-24113) on 21 and 28 August 2025 and 13 September 2025. The first two epochs used the MeerKAT S-band receiver ($\nu \approx 3$ GHz) and the third epoch used the UHF-, L-, and S-band receivers ($\nu \approx 0.81, 1.28, 3$ GHz, respectively). The MeerKAT observations were reduced and imaged by the SARA O (South African Radio Astronomy Observatory) pipeline. This resulted in a detection of diffuse resolved (*i.e.*, larger than the synthesized beam size) emission consistent with the location of the transient host galaxy, with a ma-

ior beam size of $\sim 5'' - 20''$ (although the beam is highly elongated, *e.g.*, Table 5) and an image RMS $\sim (4 - 45) \mu\text{Jy}/\text{beam}$. Note that we know that the emission must be mostly diffuse because it is not detected in the deeper, higher resolution radio images from the VLA, indicating that the emission is resolved out. Given the previous disagreement about the transient nature of the flux density measured from these observations (G. Bruni et al. 2025a,b; L. Rhodes et al. 2025; G. Bruni et al. 2025c), we re-extract a flux from the images using both a 2D Gaussian fixed to the size of the beam and a 2D Gaussian with a variable size. We then convert all flux density values to units of $\mu\text{Jy}/\text{beam}$ and find $F_\nu \approx 59 - 185 \mu\text{Jy}/\text{beam}$ that is dependent only on the frequency of the observation, not the time. Therefore, regardless of the fitting method used, the detections are consistent within 1σ with non-varying emission.

We observed SN 2025ulz with the Northern Extended Millimetre Array (NOEMA) 3mm receiver under program S25CS (PI: Laskar) on 22 August 2025. The observation used 3C345 and J1600+335 as the flux and phase calibrator, respectively. The data were reduced in GILDAS³⁵, following standard calibration procedures, and imaged using CASA v6.5.4. This resulted in a beam size of $\sim 3'' - 4''$, an image RMS of $\sim 21 \mu\text{Jy}$, and no evidence of emission.

Finally, we observed SN 2025ulz at 225.5 GHz with the Submillimeter Array (SMA) on 21 August 2025 under the POETS (Pursuit of Extragalactic Transients with the SMA) program (PI: Berger). The data were reduced and imaged using the COMPASS (Calibrator Observations for Measuring the Performance of Array Sensitivity and Stability) pipeline resulting in an RMS of $250 \mu\text{Jy}$, a beam size of $\sim 3''$, and no evidence of emission.

We do not detect any radio emission from SN 2025ulz, and we are confident that the diffuse emission detected by MeerKAT is from the host galaxy rather than the transient (also see subsection 4.4). For flux and limit extraction from all radio data (except those from the SMA, for which we use COMPASS), we fit a 2D Gaussian fixed to the synthesized beam size using the CASA task `imfit` at the location of SN 2025ulz. All limits are three times the RMS noise in a nearby empty portion of the sky. Our radio observations are summarized in Table 5.

4. ANALYSIS & DISCUSSION OF SN 2025ulz

4.1. *The Light Curve and Spectrum are Consistent with SNe I Ib*

Figure 3 shows the *gri* optical light curve of SN 2025ulz compared to the *gr* light curves of KN AT 2017gfo (V. A. Villar et al. 2017) and two SNe I Ib: SN 2022hnt (J. R. Farah et al. 2025) and SN 2016gkg (L. Tartaglia et al. 2017). For reference, we show the numerical model fits to SN 2016gkg from A. L. Piro et al. (2017). For SN 2025ulz we include the *i*-band to fill in the gaps and guide the eye, as it evolves similarly to the *r*-band light curve. As shown in Figure 3, SN 2025ulz follows a similar photometric evolution to both SN 2016gkg and SN 2022hnt, with all three showing a reddening ~ 2 days after explosion and a re-brightening $\sim 5 - 7$ days after explosion. In addition, Figure 3 shows that, at all times, the $g - r$ color evolution of SN 2025ulz is comparable to that of other SNe I Ib. Given that this re-brightening is inconsistent with KN models, the overall light curve of SN 2025ulz is more similar to that of an SNe I Ib than a KN.

Figure 4 shows the optical spectrum of SN 2025ulz from our MMT Binospec observation at phase ~ 12 days post-discovery. We also show optical spectra of SN 2022hnt (J. R. Farah et al. 2025), SN 2016gkg (L. Tartaglia et al. 2017) and AT 2017gfo (E. Pian et al. 2017) for comparison. SN 2025ulz shows a broad P-Cygni H α line, which we attribute to the SN, with a narrow H α component, which we attribute to the host galaxy. SN 2022hnt shows a P-Cygni H α line with an absorption component with a similar velocity ($v \sim 13,000$ km s $^{-1}$) to SN 2025ulz ($v \sim 15,600$ km s $^{-1}$) at a similar phase. In contrast, AT 2017gfo shows no strong spectral features at this phase, including a lack of any Hydrogen. Furthermore, KNe are relativistic transients with extremely fast outflows (dynamical ejecta velocities $v_{ej} \sim (0.1 - 0.3)c$; D. Kasen et al. 2017), generally expected to be faster than the velocity of the hydrogen line in the SN 2025ulz spectrum. Therefore, based on the broad P-Cygni H α line, the spectrum of SN 2025ulz is consistent with an SNe I Ib classification and inconsistent with a KN.

4.2. *Modeling the Light Curve as a KN*

For completeness, we attempt to fit the SN 2025ulz light curve as a conventional KN (*i.e.*, AT 2017gfo-like) using the models from D. Kasen et al. (2017). The D. Kasen et al. (2017) model grid produces spectral evolution models for KNe spanning dynamical ejecta velocities $v_{ej} \approx (0.03 - 0.4)c$, ejecta mass $M = (0.001 - 0.1)M_{\odot}$, and lanthanide fraction $X_{lan} = 10^{-9} - 10^{-1}$. We take their spectral model data and integrate the sim-

ulated spectrum convolved with the SDSS *r*-band transmission function to extract a simulated light curve for each model. For each model in their grid, we downsample the simulated light curve to our temporal coverage and compute the sum of the square residual ($\Sigma\epsilon^2$) with respect to our *r*-band light curve. We note that, since we are not interpolating over the D. Kasen et al. (2017) grid, this approach only produces approximations of the KN parameters. Exact KN parameters could be derived from a more detailed modeling of the SN 2025ulz light curve using existing Bayesian fitting codes (e.g., MOSFiT, J. Guillochon et al. 2018; gwemopt, M. W. Coughlin et al. 2018, 2019; nmma, P. T. H. Pang et al. 2023; redback N. Sarin et al. 2024), something that is out of the scope of this work.

We then find the best-fitting model for both the early light curve decline (≤ 6 days since explosion) and the entire light curve. The early light curve fit has a low $\Sigma\epsilon^2 = 1.66$ and the full light curve fit has a poor $\Sigma\epsilon^2 = 118.55$. As a result, in Figure 3 we show the best-fit model (lowest $\Sigma\epsilon^2$) for the early light curve as a solid line. This demonstrates that the early light curve can be fit well with a conventional KN model, but not the full light curve. The early time best-fit model has an ejecta mass of $M_{ej} \approx 0.05 M_{\odot}$, outflow velocity of $v_{ej} \approx 0.2c$, and a lanthanide mass fraction $X_{lan} \approx 10^{-2}$. In contrast, the best-fit model for the entire light curve, which is an extremely poor fit, has $M_{ej} \approx 0.01 M_{\odot}$, $v_{ej} \approx 0.03c$, and $X_{lan} 10^{-9}$.

Based on this analysis, no model in the D. Kasen et al. (2017) grid is able to reproduce the luminosity of the second optical peak while simultaneously capturing the early time light curve features. This is expected given that the optical luminosity of the first peak requires a high X_{lan} while the optical luminosity of the second optical peak requires a small X_{lan} (D. Kasen et al. 2015). Furthermore, even though D. Kasen et al. (2015) predict a second peak in the *infrared*, we are not aware of any conventional KN model, irrespective of the viewing angle, that has a second *optical* light curve peak more luminous than its initial peak (as is seen in SN 2025ulz).

We briefly consider, and subsequently disfavor, more extreme and irregular KN models. One model for GW signals from a subsolar-mass (SSM) BNS merger is the fragmentation of a collapsar disk into multiple, low-mass NSs that later merge (B. D. Metzger et al. 2024; Y.-X. Chen & B. D. Metzger 2025). Under this model, we would expect an SN followed by multiple GW signals, with the last signal consistent with a NSBH/BNS merger (almost certainly with a chirp mass $\gtrsim 1M_{\odot}$) that occurs $\sim$ hours-days after the initial GW signal (B. D. Metzger et al. 2024). In the case of S250818k, there was only

one (low-significance) GW signal reported from its localization region (*e.g.*, as was noted in J. H. Gillanders et al. 2025). However, it is possible, given the model parameters, that LVK only detected the strongest of the many predicted signals. While we can not entirely rule out this model, we strongly disfavor it given the overwhelming observational similarities between SN 2025ulz and other prototypical SNI Ib, making the SN explanation considerably more plausible.

Related, the SNI Ib SN 2025uso was discovered ~ 2 days after S2501818k and is in the localization volume of the event (K. C. Chambers et al. 2025). Based on publicly available light curve information, the explosion date of this event is roughly consistent with the S2501818k merger date ($\delta t \sim -1$ days, similar to our computed explosion date for SN 2025ulz). Under the B. D. Metzger et al. (2024) model for KN from SSM BNS mergers, SN 2025uso should be considered an equally likely candidate KN associated with S2501818k. However, we rule this out for the same reasons as SN 2025ulz; the simpler, prototypical SN explanation is much more plausible.

Another possible KN model is an extreme eccentric encounter between a NS and a BH. Under this model, the NS initially approaches on an orbit grazing the tidal radius of the BH and then on the next orbit is fully disrupted. This, in theory, can explain two electromagnetic flares (at the pericenter of both orbits) with only one GW signal (at the time of the full disruption of the NS; W. E. East et al. 2015). This model is rather unlikely, as (1) it would require a very extreme initial orbit to explain the timescales of the two flares in the optical light curve; (2) the International Gravitational Wave Network (IGWN) alert had a $\sim 0\%$ probability that this was a NSBH merger; (3) the *maximum* chirp mass is $0.87 M_\odot$, indicating a hypothetical black hole mass $\lesssim 1 M_\odot$ and making this scenario extremely unlikely; and (4) it predicts the formation of an accretion disk, rather than the expanding outflow that is required to produce the P-Cygni H α profile in our optical spectrum. Therefore, we also rule out this model.

4.3. Early Shock Cooling Light Curve Modeling

Shock cooling in type Ib SNe occurs when the explosion shock wave deposits energy into the progenitor’s extended, partially stripped hydrogen envelope, which then radiates its residual thermal energy as it rapidly expands and cools in the subsequent hours to days following shock breakout (M. W. Richmond et al. 1994; S. E. Woosley et al. 1994; N. Sapir & E. Waxman 2017; I. Arcavi et al. 2017). We fit the early ($\delta t \lesssim 7$ days since discovery) light curve dataset of SN 2025ulz to semi-analytic shock cooling models described by N. Sapir &

E. Waxman (2017), using a Markov Chain Monte Carlo (MCMC) routine implemented in the Light Curve Fitting package (G. Hosseinzadeh et al. 2024). We follow the same methods for the early shock cooling light curve modeling for type Ib as described in B. M. Subrayan et al. (2025). Two polytropic indices ($n = 3/2$ and $n = 3$) were considered to represent convective (Red Supergiant; RSG) and radiative (Blue Supergiant; BSG) progenitor envelopes. The MCMC simultaneously constrains the progenitor radius (R), shock velocity (v_s), and envelope mass (M_{env}), while an intrinsic scatter term (σ) scales the observational errors by $\sqrt{1 + \sigma^2}$ to account for additional variance. A scaled ejecta mass parameter was also included but remains largely unconstrained due to its minimal impact on the early light curve. The best fit models and the derived parameters for RSG and BSG progenitors are shown in Figure 5.

The early-time light curve of SN 2025ulz is well described by the semi-analytic shock cooling models of N. Sapir & E. Waxman (2017), with the inferred envelope mass M_{env} and progenitor radius R falling within the parameter space spanned by known type Ib events in the literature, as shown in Figure 6. The best-fit values of SN 2025ulz lie closest to SN 2022hnt and SN 2016gkg. This is also consistent with the spectral similarity between the two SNe at $\sim +12$ days (see Figure 4). The inferred M_{env} and R for SN 2025ulz also match the theoretical ranges predicted by S.-C. Yoon et al. (2017) and N. Sravan et al. (2020) for RSG progenitors with residual, thin hydrogen envelopes, typical of SNI Ib that display P-Cygni H profiles in their spectra. We also note that the modeling yields an explosion epoch that consistently precedes the reported subthreshold GW event. However, this model can overestimate the rise time of the SN and may produce explosion epochs before the true explosion date (J. Pearson et al. 2023).

4.4. Host Galaxy Properties Reveal a Star-Forming Galaxy

The star formation rate (SFR) of a host galaxy can provide important contextual information for the classification of transients. For example, due to the short lifetimes of their high mass progenitors, core collapse SNe (CCSNe) are expected to occur at a higher rate in galaxies with active star formation. We use the results from Blast³⁶, a web service and automated galaxy spectral energy distribution modeling software, to infer the physical properties of SN 2025ulz’s host galaxy (D. O. Jones et al. 2024). For SN 2025ulz, Blast finds a stellar mass $M_* = 1.23^{+0.21}_{-0.15} \times 10^{10} M_\odot$, $\text{SFR} = 0.298^{+0.244}_{-0.143} M_\odot \text{ yr}^{-1}$,

³⁶ <https://blast.ncsa.illinois.edu/>

Figure 5. Fits of the *griI* and HST F336W (which is comparable to Swift/UVOT *U*-band) light curves of SN 2025ulz with a shock cooling modeling (N. Sapir & E. Waxman 2017), assuming two polytropic indices: $n = 3/2$ (left) and $n = 3$ (right). The best-fit explosion date, with uncertainties, and the detection date of S250818k are shown as grey and purple dashed lines, respectively.

and a specific SFR $\text{sSFR} = 2.37^{+2.02}_{-1.19} \times 10^{-11} \text{ yr}^{-1}$. This SFR and host galaxy mass are consistent with the broader population of type IIb SNe (Y.-J. Qin & A. Zabludoff 2024; A. E. Nugent et al. 2025). We now explore other probes of star formation rate including $\text{H}\alpha$, which probes star formation in the last 10 Myr, and the diffuse radio emission observed in MeerKAT, which probes the last 150 Myr (R. C. Kennicutt & N. J. Evans 2012).

Since no emission at the location of SN 2025ulz was visible in our Keck spectrum, we instead extracted a host galaxy spectrum. We first estimate the host extinction $E(B - V)$ using the Balmer decrement. We model both the $\text{H}\alpha$ and $\text{H}\beta$ lines with a Gaussian plus a linear continuum³⁷. The model of $\text{H}\alpha$ is shown in Figure 7. We integrate both the $\text{H}\alpha$ and $\text{H}\beta$ best fit models to obtain the line flux. From the $\text{H}\alpha/\text{H}\beta$ ratio we find a host extinction of $E(B - V) \approx 0.49 \text{ mag}$ using the relations from A. Domínguez et al. (2013). This extinction is for the entire host galaxy and is likely overestimated along

the line of sight to SN 2025ulz, as its location is outside the plane of the host galaxy and we do not detect Na II in the MMT Binospec spectrum of the transient.

As a check on the Blast values, we compute the SFR and sSFR from $\text{H}\alpha$. By assuming a Milky Way $R_V = 3.1$, we correct the $\text{H}\alpha$ line flux for both host and Milky Way dust extinction using the `extinction` Python package. We apply the relation from R. C. Kennicutt (1998) to obtain a host galaxy star formation rate $\text{SFR} \approx 0.8 \pm 0.2 \text{ M}_\odot \text{ yr}^{-1}$, or $\text{sSFR} \approx 8 \times 10^{-11} \text{ yr}^{-1}$, from the $\text{H}\alpha$ line flux. This is consistent, but at the upper end of the uncertainty, with the SFR derived by Blast.

The third epoch of MeerKAT observations was performed at the UHF-, L-, and S-bands. This allows us to derive a spectral index for the diffuse emission of $\alpha \sim -0.9$, which is consistent with observations of star forming galaxies (F. An et al. 2024). Using this spectral index and the relations from E. J. Murphy et al. (2011), we find $\text{SFR} \sim 5 \text{ M}_\odot \text{ yr}^{-1}$. Given the $\sim \text{dex}$ scatter in both relations used, and because the radio probes a longer epoch of star formation, the radio and $\text{H}\alpha$ derived SFR are broadly consistent. This consistency is further evidence that the diffuse radio emission

³⁷ Additionally, we add a [N II] and [S II] Gaussian component to our $\text{H}\alpha$ model.

Figure 6. The shock cooling model envelope mass vs. progenitor radius for SN 2025ulz as compared to a population of SNe I Ib. SN 2025ulz lies in a similar region of parameter space to the other SNe I Ib and is in nearly the same region as SN 2016gkg using the same model. SNe highlighted in bold have values derived from similar shock-cooling modeling, while the others adopt values from alternate methods. Points with the right half filled are from the N. Sapir & E. Waxman (2017) BSG model and points with the left half filled are from the N. Sapir & E. Waxman (2017) RSG model. Published values for other SNe in this figure are obtained from: SN 1993J: S. E. Woosley et al. 1994; SN 2008ax: A. Pastorello et al. 2008; R. A. Chevalier & A. M. Soderberg 2010; SN 2011dh M. C. Bersten et al. 2012; SN 2011ei: D. Milisavljevic et al. 2013; SN 2011fu: A. Morales-Garoffolo et al. 2015; SN 2013df: A. Morales-Garoffolo et al. 2014; SN 2016gkg: I. Arcavi et al. 2017; SN 2017jgh: P. Armstrong et al. 2021; SN 2020bio: C. Pellegrino et al. 2023; SN 2022hnt: J. R. Farah et al. 2025; SN 2024uwq: B. M. Subrayan et al. 2025, SN 2024abfo: A. Reguitti et al. 2025; and K. K. Das et al. 2023.

detected by MeerKAT is consistent with star formation in the past ~ 150 Myr.

Qualitatively, the combined evidence from Blast, our radio observations, and our $H\alpha$ measurements indicate a consistently high SFR over the past ~ 100 Myr ($\sim 1 M_{\odot} \text{ yr}^{-1}$) for the host galaxy of SN 2025ulz. The SFRs computed here make the SN 2025ulz host consistent with the larger population of CCSN hosts presented in Y.-J. Qin & A. Zabludoff (2024); A. E. Nugent et al. (2025)

Figure 7. Model of our Keck spectrum that is dominated by emission from the SN 2025ulz host. We use this model to derive a star formation rate for the host galaxy for comparison with our radio derived star formation rate.

but, alone, does not necessarily rule out a BNS origin (e.g., K. Belczynski et al. 2017).

4.5. The Radio Observations Rule Out a SGRB-like On-Axis Jet

In contrast to the low-resolution ($\sim 10''$) MeerKAT observations, our higher-resolution ($\sim 1''$) GMRT, VLA, NOEMA, and SMA observations probe the existence of compact radio emission components. We do not detect radio emission at the transient position with any of these telescopes and we show the light curve of the radio upper limits in Figure 8. For comparison, we show the radio data for AT 2017gfo, SN 2016gkg, and a sample of SGRBs from the literature.

These early-time radio upper limits on SN 2025ulz rule out an on-axis jet like those seen in SGRBs, which would be expected for a face-on BNS merger (e.g., G. Schroeder et al. 2025). However, our limits are still consistent with a BNS merger with an off-axis jet that only brightens in the radio after ~ 10 days, like AT 2017gfo. Our radio limits are also consistent with the less luminous radio emission produced following a CCSN and, in particular, is consistent with the luminosity of the SN I Ib 2016gkg (see Figure 8).

5. A SEARCH FOR ADDITIONAL KILONOVAE CANDIDATES

Given the overwhelming photometric and spectroscopic evidence that SN 2025ulz is a type I Ib SNe and not a counterpart to S250818k, we search the TNS for other transients (1) with coordinates inside the 95% localization region for S250818k from the IGWN data stream and (2) reported within one week of the discovery of S250818k. This search reveals 121 electromag-

Figure 8. The radio light curves of SN 2025ulz (downward triangles as limits) as compared to SN 2016gkg (squares; [N. A. J. et al. 2022](#)), a sample of short SGRB radio detections (diamonds; [E. Berger et al. 2005](#); [A. M. Soderberg et al. 2006](#); [W. Fong et al. 2014, 2015](#); [G. P. Lamb et al. 2019](#); [W. Fong et al. 2021](#); [T. Laskar et al. 2022](#); [W.-f. Fong et al. 2022](#); [A. E. Nugent et al. 2024](#); [G. Schroeder et al. 2024](#); [A. J. Levan et al. 2024](#); [G. Schroeder et al. 2025c](#); [Dimple et al. 2025](#); [A. J. Nayana & P. Chandra 2014](#); [G. E. Anderson et al. 2024](#); [J. An et al. 2025b](#); [G. Schroeder et al. 2025a](#); [R. Ricci et al. 2025a](#); [W. Fong et al. 2025](#); [G. Schroeder et al. 2025b](#); [L. Rhodes et al. 2023](#); [A. J. Levan et al. 2009](#); [R. Ricci et al. 2025c](#)), and AT 2017gfo (plus signs; [K. D. Alexander et al. 2017](#); [G. Hallinan et al. 2017](#); [S. Kim et al. 2017](#); [S. Makhathini et al. 2021](#); [G. Hallinan et al. 2017](#); [K. P. Mooley et al. 2018a,b,c](#); [L. Resmi et al. 2018](#); [K. P. Mooley et al. 2018b,a](#); [D. Dobie et al. 2018](#); [K. P. Mooley et al. 2018a,a](#); [R. Margutti et al. 2018](#); [J. W. Broderick et al. 2020](#); [D. Dobie et al. 2018](#); [G. Ghirlanda et al. 2019](#); [K. D. Alexander et al. 2018](#); [E. Troja et al. 2019](#); [A. Hajela et al. 2019](#)). The color of the point is the representative frequency of the receiver used for the observation. Our radio limits on SN 2025ulz rule out an SGRB-like on-axis jet but do not rule out SN IIB-like or late-rising AT2017gfo-like radio emission.

netic candidate counterparts, one of which is SN 2025ulz. This suggests that the KN search after S250818k (and likely other GW events, see [K. Ackley 2025](#)) would have benefited from follow-up of additional candidates.

Expanding on the method in [J. C. Rastinejad et al. \(2022\)](#), we vet these candidates to determine the likelihood of association with S250818k. For each step in their vetting process, we develop a scoring algorithm that quantifies our confidence in the association of a transient with the GW event. Our scoring procedure consists of four components:

1. Score from the 2D localization ([subsection 5.1](#))
2. Score from the distance localization ([subsection 5.2](#))

3. Score from comparison to known asteroids and point source/variability catalogs ([subsection 5.3](#))
4. Score from comparing the photometric evolution to models and existing observations ([subsection 5.4](#))

Finally, we take the resulting score from each of these components and multiply them to obtain a total score between 0 and 1, such that a higher score generally indicates a more probable candidate.

A summary of this scoring is shown in [Figure 9](#) and details are presented in the following subsections. For reference, we validated this scoring algorithm against AT2017gfo and found that it has a score of $S \approx 0.55$, depending on if we use the photometric redshift (from the best matching host, $S = 0.54$) or spectroscopic redshift ($S = 0.56$). This score of ~ 0.55 for the known kilonova counterpart to a BNS merger suggests that a candidate need not have a score of ~ 1 to be worth consideration.

5.1. 2D Localization Score

The IGWN localization map for GW events provides a probability density in each HEALPix tile describing the likelihood that the GW event originated from that tile. These probability densities are normalized such that integrating over the entire sky provides a localization probability of 1.0. We extract the probability density from the HEALPix tile where each candidate is located and perform a 2D integration over the localization region with a higher probability density ([L. P. Singer et al. 2016a,b](#)). This cumulative probability is the score that the GW event originated from the candidate coordinates³⁸, and is the 2D localization score (S_{2D}).

5.2. Distance Score

Deriving a distance score requires distances for both the GW signal and the candidate electromagnetic counterpart. The distance to the GW event is given as a function of localization tile, where each tile in the localization map has an associated distance and uncertainty ([L. P. Singer et al. 2016a,b](#)). We use the distance in the tile corresponding to the candidate coordinates as the distance to the GW event when computing the distance score for this candidate.

Finding the distance to the candidate is more difficult, since the redshift is typically not known. Therefore, we

³⁸ Since we use the cumulative probability, the score is less dependent on the NSIDE property of the HEALPix map, as compared to using the probability density.

Figure 9. Flow diagram outlining our current candidate scoring algorithm. In general, it takes in IGWN alerts, TNS transients, various static catalogs, and forced photometry and derives multiple “subscores” from the data, eventually multiplying them together to obtain a total overall score for a candidate.

first query galaxy redshift catalogs³⁹ for all potential host galaxies within $2'$ (≈ 150 kpc at 260 Mpc) of the candidate. Note that we expect this host galaxy search to be relatively complete at $z \leq 0.3$, the distance scale that is relevant for this work, because LS DR10 is $> 90\%$ complete out to this redshift (C. Li et al. 2024). For each galaxy match found, we compute the probability of chance coincidence (P_{cc} ; J. S. Bloom et al. 2002). We select all galaxies with $P_{cc} < 0.1$ as potentially associated with the candidate. If no galaxies have $P_{cc} < 0.1$, we select the galaxy with the minimum P_{cc} as the most likely host.

After finding the most probable host galaxies for the candidate, we extract the redshift and uncertainties from the respective catalog. From this we derive a distance probability distribution for each host galaxy. The distance score S_{dist} is then the integrated joint probability of the host distance distribution and the GW distance distribution, derived along the line of sight to the

transient (see Equation A4). Since we apply this approach to all host galaxies potentially associated with a candidate, and since the photometric redshifts of these galaxies may have unknown systematic uncertainties, we downweight the distance score by selecting the highest score among all potential host galaxies for this candidate. More details on the method used for this calculation are given in Appendix A.

5.3. Minor Planet and Point Source Catalog Comparison

We perform a cone search on the ASAS-SN (All-Sky Automated Survey for Supernovae) Variable Star catalog X (B. J. Shappee et al. 2014; C. T. Christy et al. 2023), Gaia Data Release 3 Variable Star catalog (Gaia Collaboration et al. 2023b), and Pan-STARRS (PS1) Point Source catalog (R. Beck et al. 2021) for any targets within 2 arcseconds of the candidate. If a match is found then it indicates, *e.g.*, a flaring star rather than a KN, and we assign a point source score of $S_{\text{PS}} = 0$. Otherwise, if no match is found in these catalogs, we assign $S_{\text{PS}} = 1$.

We also pull the file of asteroid ephemerides from the Minor Planet Center (MPC)⁴⁰. Using simple 2 body evo-

³⁹ These include DESI (Dark Energy Spectroscopic Instrument) Early Data Release (DESI Collaboration et al. 2024), GLADE (G. Dály et al. 2018), GWGC (Gravitational Wave Galaxy Catalog) (D. J. White et al. 2011), Hecate (K. Kovlakas et al. 2021), LS DR10 (Legacy Survey Data Release 10) (R. Zhou et al. 2023), Pan-STARRS (PS1) Galaxy catalog (R. Beck et al. 2021), and SDSS DR12 (Sloan Digital Sky Survey Data Release 12) photo- z catalog (S. Alam et al. 2015).

⁴⁰ <https://www.minorplanetcenter.net/>

lution around the Sun we find all asteroids that are approximately within 10 degrees of the candidate location at the time of the first photometric detection. For any asteroid found in this initial search we perform a full n -body evolution to find the more precise location at the time of the first photometric detection of the candidate. This is implemented using the `kete` Python package (D. Dahlen et al. 2025). If a match is found within $25''$ of the candidate, it receives an MPC score of $S_{\text{MPC}} = 0$, otherwise it receives a score $S_{\text{MPC}} = 1$. $S_{\text{MPC}} \times S_{\text{PS}}$ is the final score for this portion of the analysis.

5.4. Photometry Scoring

We score candidates with available photometry by comparing basic metrics from their light curve properties to both AT2017gfo and KN models (see below). Throughout the photometry scoring we choose a minimum score of 0.1. This, in effect, prevents a single photometric anomaly in the light curve from completely ruling out the candidate. This is a way to “soften” the effects of the assumption that all KNe look like the existing models.

We first check for pre-detections in the ATLAS forced photometry for the 181 days prior to GW event S250818k. We only consider 5σ detections with at least 2 other 5σ detections within the range ± 5 days. If any pre-detections are discovered, we assign a score of $S_{\text{pre}} = 0.1$, otherwise $S_{\text{pre}} = 1$.

For candidates with more than one detection after the GW discovery date, we also compare the rise time, decay rate, and peak luminosity to KNe models. To extract these properties from the candidate light curves we first gather all optical photometry in the g , r , i , ATLAS- c , or ATLAS- o filters⁴¹. We then fit the light curve with both a power law and a broken power law. We only fit a broken power law to the data if more than 5 photometric detections are available; otherwise, the model does not have enough constraining power.

After fitting both models to the photometry, we choose the model with the lowest Akaike Information Criterion (AIC)⁴². From the light curve model we derive a decay rate and a rise time. KN models show that, in all cases, the light curve should decay at a rate faster than 0.1 mag day^{-1} (e.g., D. Kasen et al. 2015, 2017; C. D. Kilpatrick et al. 2021; J. C. Rastinejad et al. 2022).

Therefore, for any decay rate $< 0.1 \text{ mag day}^{-1}$ we assign a decay rate score of $S_{\text{DR}} = 0.1$, otherwise $S_{\text{DR}} = 1$. Similarly, no KN models have a rise time greater than 4 days long (e.g., D. Kasen et al. 2015, 2017; C. D. Kilpatrick et al. 2021; J. C. Rastinejad et al. 2022). We therefore require the peak of the light curve to occur less than 4 days after the GW event. If the peak occurs after 4 days the candidate receives a score $S_{\text{RT}} = 0.1$, otherwise $S_{\text{RT}} = 1$.

Finally, we also compute the maximum luminosity using the maximum observed flux in the light curve (not the maximum flux of the model) at the distance to the GW event along the line of sight to the candidate. Since the maximum mass of a neutron star sets an upper limit on the maximum outflow mass, we can conservatively assume that a KN should not have a luminosity $\nu L_{\nu} > 10^{43} \text{ erg s}^{-1}$ (e.g., D. Kasen et al. 2015, 2017; C. D. Kilpatrick et al. 2021; J. C. Rastinejad et al. 2022). Any candidate with $\nu L_{\nu} > 10^{43} \text{ erg s}^{-1}$ receives a score $S_{\text{L}} = 0.1$, otherwise $S_{\text{L}} = 1$. To obtain a final photometry score, we multiply all of the previously discussed photometry subscores, to obtain $S_{\text{P}} = S_{\text{PD}} \times S_{\text{DR}} \times S_{\text{RT}} \times S_{\text{L}}$.

5.5. Application to S250818k

In the case of the BNS GW event S250818k, we find 121 candidates with the scores summarized in Table 2 (and the full score information is in Table 3). The locations of these candidates with respect to the GW localization map is shown in Figure 1. SN 2025ulz receives a score of $S \approx 0.0011$ as a result of both its distance ($S_{\text{dist}} \approx 0.16$) and photometric evolution ($S_{\text{phot}} \approx 0.01$). We discuss SN 2025ulz in more detail in subsection 5.6.

We briefly discuss the other high scoring candidates given in Table 2. $41/121 \approx 34\%$ of the candidates have a score $S \geq 0.01$ and, of those 41, only 18 have more than one photometry point. We visually inspect those 18 transients to identify a subset of interest to discuss in more detail. In particular, we ignore candidates with poor host association (i.e., the host used for the distance score is clearly not related to the transient position, e.g., AT 2025utu), the best matching host galaxy has a distance $> 1000 \text{ Mpc}$ (e.g., AT 2025uog)⁴³, and/or those that have multiple photometry points but all in different filters (e.g., AT 2025vag). We find two promising candidates, AT 2025uow (J. Tonry et al. 2025) and AT 2025uxu (A. Salgundi 2025), but none with enough

⁴¹ Since we are trying to derive the properties of the bulk evolution of the light curve it is safe to assume that these evolve relatively similarly.

⁴² The AIC score takes the model complexity into account for model comparison to help ensure we are not overfitting. We also tried the Bayesian Information Criterion and it did not make a difference.

⁴³ The transients that fall into this category typically lie in a HEALPix tile with an unusually high distance uncertainty and have a photometric distance with an unusually high uncertainty. This combination results in the transient not being ruled out by its distance during the automated scoring.

Table 2. Top Candidate Scores and SN 2025ulz (Full Table in [Appendix B](#))

TNS Name	RA (deg)	Dec (deg)	Overall Score	2D Score	Point Source Score	Distance Score	Peak Luminosity (erg s^{-1})	Time of Peak ^a (days)	Decay Rate ^a (mag day^{-1})	Pre-Detection Score

^a An empty row indicates that there was only one public photometry point, which is not enough to fit the light curve and compute this value. We therefore do not consider a score from this value when computing the total score.

Figure 10. Light curves of the publicly available data from ATLAS and TNS on AT 2025uxu (blue) and AT 2025uow (red) as compared to AT 2017gfo (black; V. A. Villar et al. 2017). We scale the observed magnitudes of AT 2025uxu and AT 2025uow to the mean distance in the corresponding HEALPix tile in the localization map of S250818k. The merger date associated with S250818k is shown as a grey dashed vertical line. Different markers indicate different telescope filters.

information to unambiguously prove whether or not they are KNe, suggesting a more comprehensive follow-up strategy of transients found in the localization volume of a GW event would be beneficial for the community. The light curves of both of these candidates are in Figure 10.

AT 2025uow has a total score of 0.38, mostly due to its $S_{2D} = 0.45$. The light curve reveals a rapid decline at a rate of $0.13 \text{ mag day}^{-1}$, a red color (based off of only one epoch with an ATLAS c and o filter observation within 1 day of each other), and a peak luminosity $\nu L_{\nu} \approx 2 \times 10^{42} \text{ erg s}^{-1}$. All three of these photometric properties are consistent with KNe models. However, there is one significant ATLAS predetection at $\delta t \approx -2$ days. Based on this predetection, the light curve appears to *peak*, rather than begin to rise, near the discovery of S250818k, making it unlikely that this is a KN associated with a BNS merger.

AT 2025uxu has a score of 0.24, primarily because of its 2D localization score of 0.3, and only two photometric detections in the ZTF g -band following the discovery of S250818k. These two detections fade at a rate of $\sim 0.25 \text{ mag day}^{-1}$ and have a peak luminosity $\nu L_{\nu} \approx 5 \times 10^{41} \text{ erg s}^{-1}$, both consistent with KNe models. However, we have no color information and the ATLAS upper limits from before the discovery of S250818k are non-constraining. Therefore, given this lack of information, we hesitate to draw any conclusions for this object.

J. H. Gillanders et al. (2025) finds seven other candidates associated with S250818k, all of which they rule out. Based on our algorithm, six of these candidates, with the exception of AT 2025uuf, receive a score $S \approx 0$ (Table 3). AT 2025uuf has the second highest score ($S = 0.51$) of all of our candidates. However, only the Pan-STARRS photometry reported to TNS is publicly available, and the ATLAS limits are non-constraining based on the Pan-STARRS detection. Therefore, we defer to the conclusion of J. H. Gillanders et al. (2025) that AT 2025uuf is inconsistent with a KN.

5.6. Temporal Evolution of the SN 2025ulz Score

The public GCNs for the follow-up of SN 2025ulz provide a unique opportunity to apply this scoring algorithm as a function of time. In this way, we can demonstrate how the score changes as more information is found on the transient. To do this we account for:

1. The release of new IGWN alerts with updated skymaps. This affects both the 2D score and distance score.
2. The measurement of a spectroscopic redshift by V. Karambelkar et al. (2025) of SN 2025ulz at ~ 2.6 days after the discovery of the GW event. This affects the distance score.
3. The announcements of new photometric measurements of SN 2025ulz. We do this by fitting the data binned in one day increments. Note that we do not include the Pan-STARRS light curve from J. H. Gillanders et al. (2025) because it was not made public until after the time period considered here.

The minor planet and point source scores are held constant at $S_{PS} = S_{MPC} = 1$ since SN 2025ulz is not found to spatially coincide with any known point sources or asteroids.

In the bottom panel of Figure 11 we show the evolution of the 2D, distance, photometry, and total score. In the top panel we show the evolution of the light curve models used for extracting the photometry score. The distance score is strongly affected by the measurement of a spectroscopic redshift because the scoring algorithm switches from using a photometric redshift with large, asymmetric uncertainties to a spectroscopic redshift with small uncertainties, which we set to $\delta z = 10^{-3}$. This, in effect, treats the spectroscopic redshift distance measurement as a delta function, lowering the distance score from $S_{\text{dist}} = 0.71 \rightarrow 0.16$.

The photometry score for SN 2025ulz is initially very high with a score $S_P = 1$. This is because the light curve

Figure 11. *Top:* The best fit light curve after including different ranges of data. The color of the line represents the maximum δt days since discovery that was used when selecting data to fit. *Bottom:* The change in total score (red), photometry score (blue), distance score (black), and 2D score (orange) over time as we include additional information/measurements of SN 2025ulz. The distance score drops after a spectroscopic redshift is measured at $\delta t \approx 2.6$ days. After the light curve turns over, the photometry score drops, since this turnover is inconsistent with KN models and the AT 2017gfo light curve.

of SN 2025ulz initially fades quickly and peaks soon after the GW discovery date, as is expected for a KN. However, after the observations on day 6, the score drops to $S_P = 0.1$ because, after we include the day 6 photometry, the AIC score for the broken power law drops below the single power law score, indicating a better fit. This indicates that the light curve has begun to rise again and the decay rate score drops to $S_{DR} = 0.1$. At day 10 the photometry score drops again because the most recent photometry point is now more luminous than the first observation. This changes the time of peak to 10 days after the GW discovery, outside our conservative range of 0 to 4 days, and also drops the rise time score to $S_{RT} = 0.1$.

In Figure 12 we show the evolution of the SN 2025ulz score compared to the other candidates, and we show the number of candidates with a score greater than SN 2025ulz as a function of time. At the time SN 2025ulz was announced, there were 5 transients discovered with a marginally higher score than SN 2025ulz, suggesting that additional candidates were also initially consistent with a KN and would have benefited from additional

follow-up. The SN 2025ulz score drops as more observations are included, and thus more candidates have a higher score than SN 2025ulz. This increase in the number of candidates with a higher score than SN 2025ulz over time is likely caused by the lack of follow-up for these candidates, most of which are surely not KNe. With a more comprehensive follow-up strategy of multiple promising candidates the astronomical community could have continuously updated the list of promising KN candidates until each was ruled out or the true counterpart was found. Applying a similar algorithm, in real time, during future KN searches will assist with the community coordination of a comprehensive follow-up strategy.

6. SUMMARY & CONCLUSIONS

On 2025-08-20 the LVK collaboration announced the discovery of S250818k, a GW event with a 29% probability of being a BNS merger and a 71% probability of being terrestrial. Soon after, the transient SN 2025ulz was discovered at the 66% localization contour of S250818k. This prompted follow-up observations across the electro-

Figure 12. The evolution of the SN 2025ulz score (blue) as compared to the evolution of the scores of the rest of our candidates (grey). The red line shows the number of candidates with a better score than SN 2025ulz over time (right y-axis). The labels near the red line are the number of candidates with a score greater than SN 2025ulz at that time.

magnetic spectrum to determine if SN 2025ulz was consistent with KN emission following the potential BNS merger.

In this paper, we present and analyze observations of SN 2025ulz spanning from the ultraviolet to radio wavelengths. We also compare these observations against a novel scoring algorithm to determine the likelihood that a specific transient is associated with a BNS merger GW signal. Based on these observations, we find SN 2025ulz to be consistent with a SN I Ib, and inconsistent with both KN models and the KN AT 2017gfo. A summary of our findings are:

- In the first ~ 5 days after the discovery of S250818k, SN 2025ulz faded rapidly and reddened as it faded in the optical (Figure 3). This is both consistent with the broader population of SN I Ib and reminiscent of AT 2017gfo. However, starting ~ 6 days after the discovery of S250818k, the SN 2025ulz optical light curve begins to re-brighten, eventually reaching a peak luminosity at $\gtrsim 25$ days. This optical re-brightening to a more luminous second peak is consistent with an SN I Ib and inconsistent with both AT 2017gfo and KN models.
- At $\delta t \sim 2.6$ days after discovery, we find that SN 2025ulz has a combined score of $S \sim 0.45$ (Figure 11). After the measurement of the spectroscopic redshift at $\delta t \approx 2.6$ days this score drops to $S \sim 0.16$ because the spectroscopic redshift puts the distance $\sim 1.7\sigma$ above the best-fit GW distance along that line of sight.

- By applying our photometry scoring algorithm to SN 2025ulz over time we find that the early ($\delta t < 5$ days) optical light curve evolution is consistent with KN models. But, similar to our qualitative discussion above, as soon as the optical light curve begins to re-brighten around $\delta t \sim 6$ days, it is no longer consistent with a KN, and the score drops (Figure 11).
- Modeling of the initial decline in the SN 2025ulz light curve shows that it is consistent with the shock cooling expected from a SN I Ib (Figure 5). Additionally, the envelope mass and progenitor radius derived from this model are consistent with the rest of the SN I Ib population, and most similar to SN 2016gkg (Figure 6).
- The optical spectrum of SN 2025ulz (Figure 4) has a broad P Cygni $H\alpha$ line with a velocity of $\sim 15,600 \text{ km s}^{-1}$. The strength and velocity of this $H\alpha$ line is consistent with both the SN I Ib SN 2022hnt and SN 2016gkg at nearly the same phase. If SN 2025ulz were a KN we would expect a featureless spectrum, like AT 2017gfo, and a higher outflow velocity than measured from the $H\alpha$ line.
- We find no evidence for transient radio emission originating from SN 2025ulz (Figure 8). Our radio limits rule out an on-axis jet, like those seen in SGRBs, as would be expected for a face-on KN. Our radio observations do not rule out an off-axis KN like AT 2017gfo or an SN I Ib like SN 2016gkg.

- We derive a SFR from the host H α emission and diffuse radio emission from the MeerKAT observations. Both are consistent with SFR $\sim 1 M_{\odot} \text{ yr}^{-1}$, indicating that the host galaxy is actively star forming. This finding is consistent with the core collapse SN interpretation of SN 2025ulz.

When this abundance of evidence is considered in its entirety, we find that an SNIb is the most favorable interpretation of SN 2025ulz. Given this, we also apply our scoring algorithm to the 120 other transients reported to the TNS that are within the 95% region of the S250818k contour map. By doing this KN search, we find (1) 4–5 candidates more promising than SN 2025ulz at $\delta t < 2.6$ days (when the redshift was measured); (2) 19 candidates more promising than SN 2025ulz at $2.6 < \delta t \lesssim 6$ days; and (3) $\gtrsim 50$ candidates more promising than SN 2025ulz at $\delta t \gtrsim 6$ days (Figure 12). After further inspection, we find that none of these potential transients appear to be an unambiguous electromagnetic counterpart associated with S250818k — although some simply do not have enough *publicly available* photometry to draw any conclusions. In the future, a coordinated follow-up observation strategy that continues to observe all promising candidates will help shield our KNe searches against impostor SNe Iib.

With this in mind, we are building a publicly accessible website for automatically vetting candidate counterparts to poorly localized events (*e.g.*, GWs, neutrinos, poorly localized GRBs, etc.) using the quantitative scoring methodology introduced in this work. This Tool for Rapid Object Vetting and Examination (TROVE) (<https://astro-trove.github.io/>), will include both a web application and application programming interface (API) for scoring possible counterparts to poorly localized events. TROVE is under active development and will be made publicly available in the next $\sim$ year. In the future, the TROVE candidate vetting will assist with community coordination of follow-up of poorly localized events, working to prevent future contaminating transients from dominating the KN search.

Some observations reported here were obtained at the MMT Observatory, a joint facility of the University of Arizona and the Smithsonian Institution. We thank the Harvard and Northwestern teams for coordinating a joint MMT/Binospec observation with the University of Arizona.

Some of the data presented herein were obtained at Keck Observatory, which is a private 501(c)3 non-profit organization operated as a scientific partnership among the California Institute of Technology, the University

of California, and the National Aeronautics and Space Administration. The Observatory was made possible by the generous financial support of the W. M. Keck Foundation. The authors wish to recognize and acknowledge the very significant cultural role and reverence that the summit of Maunakea has always had within the Native Hawaiian community. We are most fortunate to have the opportunity to conduct observations from this mountain.

This research is based on observations made with the NASA/ESA Hubble Space Telescope obtained from the Space Telescope Science Institute, which is operated by the Association of Universities for Research in Astronomy, Inc., under NASA contract NAS 5–26555. These observations are associated with program(s) GO-17450 and GO-17805 (PI: Troja).

The National Radio Astronomy Observatory (NRAO) is a facility of the National Science Foundation operated under cooperative agreement by Associated Universities, Inc. GMRT observations were obtained for this study. We thank the staff of the GMRT who have made these observations possible. This work is based on observations carried out under project number S25CS with the IRAM NOEMA Interferometer. IRAM is supported by INSU/CNRS (France), MPG (Germany), and IGN (Spain). The Submillimeter Array is a joint project between the Smithsonian Astrophysical Observatory and the Academia Sinica Institute of Astronomy and Astrophysics and is funded by the Smithsonian Institution and the Academia Sinica. We recognize that Maunakea is a culturally important site for the indigenous Hawaiian people; we are privileged to study the cosmos from its summit.

APPENDIX

A. DETAILED METHOD FOR DERIVING THE DISTANCE SCORE

We begin with the following parameters:

- $\overline{D}_{\text{GW}}$ → The mean distance to the gravitational wave event at the position of the candidate as given by the IGWN alerts.
- σ_{GW} → The symmetric uncertainty on $\overline{D}_{\text{GW}}$ reported in the IGWN alert.
- $\overline{D}_C$ → The mean derived luminosity distance to the host galaxy with the lowest P_{cc} score.
- σ_C^+ and σ_C^- → The positive and negative uncertainties on $\overline{D}_C$, respectively. In the case of a $\overline{D}_C$ derived from a spectroscopic redshift or a photometric redshift with symmetric uncertainties $\sigma_C = \sigma_C^+ = \sigma_C^-$.

For the GW event the uncertainties are symmetric so, assuming the uncertainties are Gaussian, the probability distribution of the distance to the GW event is given by equation [Equation A1](#).

$$P_{\text{GW}}(D) = \frac{1}{\sigma_{\text{GW}}\sqrt{2\pi}} \exp \left[-\frac{1}{2} \left(\frac{D - \overline{D}_{\text{GW}}}{\sigma_{\text{GW}}} \right)^2 \right] \quad (\text{A1})$$

Since the uncertainty on the distance to the candidate event is potentially asymmetric, we use a split normal distribution ([Equation A2](#)) to describe the probability distribution.

$$P_C(D) = \sqrt{\frac{2}{\pi(\sigma_C^+ + \sigma_C^-)^2}} \times \begin{cases} \exp \left[-\frac{1}{2} \left(\frac{D - \overline{D}_C}{\sigma_C^+} \right)^2 \right], & D > \overline{D}_C \\ \exp \left[-\frac{1}{2} \left(\frac{D - \overline{D}_C}{\sigma_C^-} \right)^2 \right], & D \leq \overline{D}_C \end{cases} \quad (\text{A2})$$

The normalization factor $2/[\sqrt{\pi}(\sigma_C^+ + \sigma_C^-)]$ is derived by integrating the piecewise function from $-\infty \rightarrow \infty$. From these two probability distributions we compute the Bhattacharyya coefficient ([A. Bhattacharyya 1943](#)) — a non-parametric, normalized measure of the distances between the distributions such that 0 indicates no similarity and 1 indicates identical distributions.

$$S_{\text{dist}} = \int_0^\infty \sqrt{P_{\text{GW}}(D) \times P_C(D)} dD \quad (\text{A3})$$

$$= [\pi\sigma_{\text{GW}}(\sigma_C^+ + \sigma_C^-)]^{-1/2} \int_0^\infty \left[\exp \left[-\frac{1}{2} \left(\frac{D - \overline{D}_{\text{GW}}}{\sigma_{\text{GW}}} \right)^2 \right] \times \begin{cases} \exp \left[-\frac{1}{2} \left(\frac{D - \overline{D}_C}{\sigma_C^+} \right)^2 \right], & D > \overline{D}_C \\ \exp \left[-\frac{1}{2} \left(\frac{D - \overline{D}_C}{\sigma_C^-} \right)^2 \right], & D \leq \overline{D}_C \end{cases} \right]^{1/2} dD \quad (\text{A4})$$

where S_{dist} is the score we assign for the distance association step in our vetting algorithm. In practice, to derive a score for the distance association we integrate equation [Equation A4](#) numerically using `numpy.trapezoid` over a range $0 \rightarrow 10,000$ Mpc.

B. CANDIDATES TABLE

All of the candidates are ranked by their score in [Table 3](#).

Table 3. Candidate Scores

TNS Name	RA	Dec	Overall Score	2D Score	Point Source Score	3D Score	Peak nosity (erg/s)	Lumi- (erg/s)	Time of Peak (days)	Decay Rate (mag /day)	Pre- Detection Score
