Compton scattering is a fundamental process in QED with broad applications, yet its theoretical description at high energies is challenged by substantial next-to-leading order (NLO) corrections arising from double-logarithmic enhancements. To address this, we report the first calculation of the next-to-next-to-leading order (NNLO) total cross section with full electron mass dependence. Our analysis reveals that the NNLO correction, albeit still containing double logarithms, is numerically small due to a suppressing prefactor. By identifying the origin of these logarithms in a kinematic regime featuring a Glauber electron exchange, we successfully resum the leading logarithmic series to all orders, obtaining a compact result in terms of a modified Bessel function. The all-order structure reveals a suppression mechanism, which explains the rapid convergence of higher-order contributions. The combination of our NNLO calculation and all-orders resummation delivers a reliable and precise prediction, poised to serve the needs of high-precision experiments in the foreseeable future.

Introduction.— Compton scattering, namely the scattering of a photon with an electron, dates back to a century ago when Compton first observed the shift in photon wavelength after interacting with an electron [1], and has played an important role in the development of quantum mechanics. Nowadays, Compton scattering has been widely applied in various areas, including medical physics [2], X-ray/Gamma-ray astronomy [3], and quantum phenomena [4]. At facilities like the International Linear Collider or a future Muon Collider, Compton scattering is not only an important process that can be used to test QED predictions but also a critical tool for monitoring the beam states [5]. Frontier experiments that utilize Compton scattering as a precision means to probe the fundamental interactions require extraordinarily precise theoretical predictions.

The total cross section of Compton scattering at leading order (LO) in QED was firstly calculated by Dirac [6], Gordon [7], and then by Klein and Nishina [8] with full spin and relativistic corrections. The next-to-leading order (NLO) QED correction has been studied both numerically and analytically [9–14], with the high-energy behavior being analyzed in [14–17]. It is found that the NLO correction is substantial, ranging from 8.2% at center-of-mass energy $\sqrt{s} = 1$ GeV to around 30% at $\sqrt{s} = 1$ TeV, which largely surpasses the expectation of normal perturbative expansion in QED, i.e., $\mathcal{O}(\alpha)$ with $\alpha \sim 1/137$ being the electromagnetic coupling.

This result can be understood from the analytical form

of the total cross section at high energies [14],

$$\sigma_{\text{tot}} \sim \frac{2\pi\alpha^2}{s} \ln\left(\frac{s}{m^2}\right) \left[1 + \frac{\alpha}{6\pi} \ln^2\left(\frac{s}{m^2}\right) + \dots\right], \quad (1)$$

with m the electron mass. The double-logarithmic enhancement renders $\alpha \ln^2(s/m^2)$ of order $\mathcal{O}(1)$ at $\sqrt{s} \sim 1$ GeV, which eliminates the suppression of the coupling α at high orders. Consequently, the observed suppression at NLO stems purely from the $1/(6\pi)$ prefactor. This large logarithmic structure prompts two immediate questions: (i) whether the next-to-next-to-leading-order (NNLO) contribution still offers a significant improvement, and (ii) what is the origin of these double logarithms and how to resum them to all orders?

The double logarithms are usually related to uncancelled soft-collinear overlapping singularities. But the total cross section of Compton scattering is free of such singularities due to the Block-Nordsieck theorem [18]. Naively thinking, it only contains a singularity in the limit when the outgoing photon becomes collinear to the ingoing electron, a process called backward scattering. This corresponds to a Regge limit, i.e., $s \gg |t|$, which has been studied extensively [19–30]. The resummed leading logarithms (LLs) in the Regge limit, however, are only in the form of $(\alpha_s \ln(s/(-t)))^n$, and thus cannot be applied to the double logarithms in Compton scattering. We note that the double logarithmic terms in QED $2 \rightarrow 2$ processes at the amplitude level have been studied almost 60 years ago [31–33], which are, however, different from the result at the cross section level.

It is the purpose of this Letter to address the above two questions. We calculate the NNLO total cross section of Compton scattering by utilizing the modern multiloop techniques, which reveals further double logarithms at the high-energy limit. However, the leading logarithmic term is suppressed by a prefactor of $1/(96\pi^2)$. Based on the region analysis, we find that these logarithms emerge

¶ hfzhang@mail.gufe.edu.cn

in the region with an exchange of a Glauber electron between a bunch of collinear and a bunch of anti-collinear particles. The phase space and squared amplitude simplify significantly in this region so that we are able to predict the LLs at any order. The all-order structure clearly explains the suppressing prefactor through double factorial terms in the denominator, indicating rapid perturbative convergence for this process.

NNLO Calculation.— We focus on QED NNLO corrections to the total cross section of Compton scattering

$$e^-(p_1)\gamma(p_2) \rightarrow e^-(p_3)\gamma(p_4) \quad (2)$$

with full electron mass dependence. We do not consider contributions from final states with three charged particles because these processes can be separated experimentally. It is useful to define a dimensionless variable

$$\tau = \frac{m^2}{s} \quad (3)$$

with $s = (p_1 + p_2)^2$.

We employ **FeynArts** [34] to generate the Feynman amplitudes and use **CalcLoop** package [35] to handle Lorentz and Dirac algebras, reduce squared amplitudes to linear combinations of scalar integrals, and map the latter to predefined integral families. To apply the modern multi-loop calculation techniques, we have treated the phase space integrals as loop integrals by virtue of reverse unitarity [36–38]. The scalar integrals are then reduced to master integrals by using integration-by-part (IBP) identities [39] based on the Laporta algorithm [40]. We use the **Blade** package [41] to generate IBP identities and solve the IBP systems with the strategy of block-triangular form [42, 43], employing **FiniteFlow** [44] as a solver. Finally, we construct the differential equations [45] of the master integrals with respect to τ . We use the dimensional regularization with $\epsilon = (4 - d)/2$ to regulate both ultraviolet (UV) and infrared divergences. Instead of reconstructing the analytical ϵ dependence, we employ the strategy proposed in Refs. [46, 47] to compute only a few ϵ points. In our calculation, we take the values as $\epsilon = -1/1000$ and $\epsilon = 1/1000$ [48], combination of which results in an error of $\mathcal{O}(10^{-6})$ at the cross section level.

We fix the boundary conditions of the master integrals by the auxiliary mass flow method [49–52] implemented in **AMFlow** [46]. In principle, one can choose an arbitrary regular point in the physical region. We choose $\tau = 1/530$ close to the high-energy endpoint $\tau = 0$, which is our primary concern. Then, all results of the master integrals in the physical region can be derived by solving the differential equations. Near the singular point $\tau = 0$, we directly solve the power series expansion [53, 54] to extract the coefficients of all the logarithms $\ln^n \tau, n \leq 5$. The Frobenius series solution for the differential equations of dimensionally-regularized loop integrals has the form

$$f(\epsilon, \tau) = \sum_{a,b} \tau^a \ln^b(\tau) \left(\sum_{n=0}^{\infty} C_{abn}(\epsilon) \tau^n \right), \quad (4)$$

where b is a non-negative integer and a satisfies the pattern

$$a = a_0 + a_1 \epsilon, \quad 2a_0, a_1 \in \mathbb{Z}. \quad (5)$$

The infrared divergences cancel after real and virtual contributions are combined together. The UV divergence is renormalized in the on-shell scheme. We adopt two methods to renormalize the bare cross sections. The first is to calculate the counterterm Feynman diagrams generated by **FeynArts** and the second is to replace the bare quantities with renormalized ones. In the second method, the bare results are multiplied with the coupling constant renormalization Z_α^{OS} and wave function renormalizations $Z_2^{\text{OS}}, Z_3^{\text{OS}}$ for the electron and photon, respectively. The bare electron mass in internal propagators is replaced with the on-shell mass $m^b = m^{\text{OS}}(1 + \delta_m)$. The needed renormalization constants can be found in Refs. [55, 56]. After these manipulations, the cross section is expanded in the renormalized coupling constant α properly. The results of the two methods agree with each other.

At the end, the cross section in the full physical region $\tau \in (0, 1)$ is obtained in terms of a piecewise power series with up to 16 segments. In each expansion point, we deeply expand the power series to guarantee the high precision of the numerical result. We check and confirm our result at another regular point $\tau = 49/53$ by direct numerical computation with **AMFlow**.

The total cross section near the threshold is given by

$$\begin{aligned} \sigma(x) = & \frac{\pi\alpha^2}{m^2} \left(\frac{8}{3} - \frac{8}{3}x + \frac{52}{15}x^2 - \frac{133}{30}x^3 + \frac{572}{105}x^4 \right) \\ & + \frac{\alpha^3}{m^2} x^2 \left(-\frac{16}{9} \ln x + \frac{4}{3}x \ln x - \frac{25}{9}x^2 \ln x \right. \\ & \quad \left. + \frac{7}{15} - \frac{113}{90}x + \frac{203}{125}x^2 \right) \\ & + \frac{\alpha^4}{\pi m^2} x^2 (0.814x^2 \ln^2 x + 0.797x^2 \ln x \\ & \quad - 2.05 + 7.16x - 18.6x^2) \\ & + \mathcal{O}(x^5), \end{aligned} \quad (6)$$

where $x = (1 - \tau)/\tau$. The higher-order corrections are vanishing due to the quadratic dependence on x . This is in concordance with Thirring's theorem [12, 57, 58], which provides a strong validation of our calculation. The above expression can be used to calculate the cross section when $0.9 < \tau < 1$.

At the high-energy limit, i.e., $\tau \leq 0.01$, we provide a deep expansion with a precision that is enough for experimental needs,

$$\begin{aligned}
\sigma(\tau) = & \frac{\pi\alpha^2}{s} \left[(2L+1) + \tau(-6L+17) + \tau^2(-30L+32) + \tau^3(-70L+48) + \tau^4(-126L+64) + \mathcal{O}(\tau^5) \right] \\
& + \frac{\alpha^3}{s} \left[\left(\frac{1}{3}L^3 - \frac{1}{2}L^2 + \frac{17}{4}L - 9.5016 \right) + \tau(2L^3 + 13L^2 - 36.5340L + 0.55139) + \right. \\
& \quad \left. + \tau^2 \left(\frac{38}{3}L^3 + \frac{151}{2}L^2 - 89.091L + 47.062 \right) + \tau^3 \left(\frac{157}{3}L^3 + \frac{344}{3}L^2 - 220.07L + 149.73 \right) + \mathcal{O}(\tau^4) \right] \\
& + \frac{\alpha^4}{\pi s} \left[\left(\frac{1}{48}L^5 - 0.149L^4 + 1.34L^3 - 1.17L^2 - 16.6L + 23.8 \right) \right. \\
& \quad \left. + \tau(1.13L^5 - 6.54L^4 - 44.6L^3 + 442L^2 - 36.0L - 2.64 \times 10^3) + \mathcal{O}(\tau^2) \right], \tag{7}
\end{aligned}$$

with $L = \ln(1/\tau)$. The LO and NLO results agree with those given in [14], while the NNLO result is new. We indeed find a double-logarithmic enhancement at NNLO. Crucially, however, its leading-logarithmic coefficient is suppressed by a factor of $1/(96\pi^2)$, relative to the LO coefficient, significantly limiting its impact on the cross section. Numerically, the NNLO correction improves the NLO cross section by 0.2% at $\sqrt{s} = 1$ GeV and 2.5% at $\sqrt{s} = 1$ TeV, respectively.

For $0.01 < \tau \leq 0.9$, we provide a list of numerical values in the auxiliary file, from which the NNLO correction can be computed using interpolation.

All-Order Leading Logarithms.— Now we derive the LL of Compton scattering in the high-energy limit to all orders. The logarithm at LO comes from the phase space integration of the t -channel diagram in the backward scattering limit. It can also be considered as the imaginary part of the corresponding forward scattering loop amplitude. Using the method of regions [59, 60], we find four regions: the hard (h), collinear (c), anti-collinear ($\bar{c}$), and soft (s) regions, as in the case of $H \rightarrow \gamma\gamma$ studied in Ref. [61]. Defining two light-cone directions n_-^μ and n_+^μ along the momenta p_1 and p_2 , respectively, any momentum can be decomposed as $p^\mu = n_+ p_-^\mu/2 + n_- p_+^\mu/2 + p_\perp^\mu = (n_+ p, n_- p, p_\perp)$. The four regions correspond to the (t -channel electron) loop momentum q scaling as $\sqrt{s}(1, 1, 1)$, $\sqrt{s}(1, \lambda^2, \lambda)$, $\sqrt{s}(\lambda^2, 1, \lambda)$ and $\sqrt{s}(\lambda, \lambda, \lambda)$, respectively, with the power counting parameter $\lambda = \sqrt{\tau}$.

Direct computation of the loop amplitude in the (anti-)collinear and soft regions suffers from the problem of endpoint divergences. Imposing an analytic regulator $\nu^\eta/(n_+ q + n_- q + i0)^\eta$ to regulate such divergences, we obtain the imaginary part from only the hard and anti-collinear regions. Specifically, the hard and anti-collinear region contributions combine in the form

$$\begin{aligned}
& \text{Im} \left[\left(\frac{\mu^2}{-s - i0} \right)^\epsilon \frac{-1}{\epsilon^2} + \left(\frac{\mu^2}{m^2} \right)^\epsilon \left(\frac{\nu}{-\sqrt{s} + i0} \right)^\eta \frac{1}{\epsilon\eta} \right] \\
& = -\pi \left[\ln \frac{\mu^2}{s} - \ln \frac{\mu^2}{m^2} \right] = -\pi \ln \tau. \tag{8}
\end{aligned}$$

This result explains the origin of the logarithmic structure clearly. However, it seems redundant to introduce the analytic regulator since we do not need the cancellation of $1/\eta$ poles as in other cases [61, 62].

This regulator simply plays the role of inducing an imaginary part. Actually, the imaginary part can be obtained more intuitively from the unitarity of the S -matrix. We employ the Cutkosky rule in the anti-collinear region, forcing the photon propagator to be on-shell, i.e., taking $\delta(n_- q \sqrt{s})$, which cancels the $n_- q$ integration. The $n_+ q$ integration is also trivial due to the δ function associating with the on-shell electron propagator. Then the integral collapses to the perpendicular space $q_\perp$ integration, which generates the imaginary part in the second line of Eq. (8) directly. Therefore, applying the Cutkosky rule turns the loop momentum q from an anti-collinear mode into a Glauber mode (G), which scales as $\sqrt{s}(\lambda^2, \lambda^2, \lambda)$. In other words, the Glauber region is a subset of the anti-collinear region. It is only this region that could yield an imaginary part [63].

At NLO, the extra double logarithm can usually be caused by the soft and collinear singularities induced by the additional real or virtual photon. If the additional photon is radiated from the external electrons, the double logarithms always cancel between the corresponding virtual and real corrections which share the same topology; see an example in Fig. 1(a) and (b). Consequently, only the diagram with the additional photon emitted from the t -channel electron propagator, as shown in Fig. 1(c), could contribute to double logarithms. The full result of this diagram in the Feynman gauge is given by

$$\begin{aligned}
\sigma_{\text{ladder}}^{\text{NLO}} = & \frac{\alpha^3}{s} \left(\frac{L}{\epsilon} + \frac{1}{3}L^3 + \frac{1}{2}L^2 + L + \right. \\
& \left. \frac{5}{2} - \frac{2\pi^2}{3} - 2\zeta_3 + \mathcal{O}(\tau) \right). \tag{9}
\end{aligned}$$

The above IR divergence $1/\epsilon$ would cancel after including the renormalization of the electron wave function, which also contains IR divergences in the on-shell scheme.

The above LL is the same as that in the NLO total cross section in Eq. (7). The relevant regions for the

imaginary part of the forward scattering amplitude consist of $(q_1, q_2) \sim (h, h), (c, h), (h, \bar{c}), (c, G), (G, \bar{c})$ with q_i the momenta of electron propagators; see Fig. 1(c). Note that the overlap of (c, G) and $(G, \bar{c})$ regions is nonvanishing and thus has to be subtracted. After finding all the contributing regions, one can set the scale $\mu = \sqrt{s}$ so that the regions containing h do not produce LLs. All the LLs come only from (c, G) or $(G, \bar{c})$ or their overlap. This judicious choice of scale would simplify the calculation a lot.

FIG. 1. NLO Feynman diagrams contributing to LLs.

FIG. 2. NNLO and all-order ladder diagrams.

These structures can be extended to all orders. The t -channel electron momenta of the n -loop ladder diagram in the $N^{n-1}\text{LO}$ correction are labeled as $q_1, q_2, \dots, q_n$ respectively, as shown in Fig. 2. We adopt the notation $r_i = (c, \dots, c, G, \bar{c}, \dots, \bar{c})$ to denote the region where q_j ($j < i$) and q_k ($k > i$) are collinear and anti-collinear, respectively, while q_i is a Glauber mode. The momenta of final-state photons are denoted by $k_i, i = 0, \dots, n-1$, with $k_0 = p_4$. Momentum conservation requires $k_i = q_i - q_{i+1}$ with $q_0 = p_1$, and $p_3 = q_n + p_2$. The LL arises when the light-cone momentum components obey the strong ordering

$$n_+q_0 > n_+q_1 > \dots > n_+q_n > 0, \quad (10a)$$

$$0 < -n_-q_1 < \dots < -n_-q_n < -n_-p_2. \quad (10b)$$

The first equation (10a) always holds since $n_{\pm}k_i > 0$ and $k_i^2 = 0$, while the second equation (10b) helps chisel out the subregion contributing to LLs. It is easy to check that this subregion is contained in any of the r_i regions. Therefore, all r_i regions as well as any overlap give the same result.

The $(n+1)$ -body phase space can be written as

$$\int d\text{PS}_{n+1} = (2\pi) \int \prod_{i=1}^n \frac{d^4 q_i}{(2\pi)^3} \delta^+(p_3^2 - m^2) \prod_{j=0}^{n-1} \delta^+(k_j^2)$$

with $\delta^+(p^2) = \delta(p^2)\theta(p^0)$. Based on the strong ordering in (10) and a useful trick in dealing with LLs, i.e., dropping the smaller component in an expression, the on-shell

conditions are given by $\delta(k_0^2) \approx \delta((n_+q_0)(n_-q_0 - n_-q_1) - q_{1T}^2)$, $\delta(k_i^2) \approx \delta(-(n_+q_i)(n_-q_{i+1}) - (q_i - q_{i+1})_T^2)$, $i = 1, \dots, n-1$, and $\delta(p_3^2 - m^2) \approx \delta(n_+q_n n_-p_2 - q_{nT}^2 - m^2)$, which render the integrations of n_-q_i ($i = 1, \dots, n$) and n_+q_n trivial. Simultaneously, the squared amplitude is also simplified with the denominators $q_i^2 - m^2 \approx -q_{iT}^2 - m^2 - \frac{n_+q_i}{n_+q_{i-1}} q_{(i-1)T}^2$. Defining the variables $x_i = n_+q_i \sqrt{s}/m^2$ and $y_i = (q_{iT}^2 + m^2)/m^2$, the LL in the cross section is given by

$$\sigma_{\text{LL}}^{N^{n-1}\text{LO}} = \frac{4\pi^2}{s} \frac{\alpha^{n+1}}{(2\pi)^n} \int_1^{1/\tau} \frac{dx_1}{x_1} \prod_{j=2}^{n-1} \int_1^{x_{j-1}} \frac{dx_j}{x_j} \times \int_1^{x_1} \frac{dy_1}{y_1} \prod_{i=2}^{n-1} \int_{\max\{1, \frac{x_i}{x_{i-1}} y_{i-1}\}}^{x_i} \frac{dy_i}{y_i} \int_1^{x_{n-1}} \frac{dy_n}{y_n}, \quad (11)$$

where we have replaced the dimensional regularization of the divergences by a cutoff regularization. The lower bound of x_j and upper bound of y_j with $j = 1, \dots, n-1$ are determined since q_j is supposed to be a collinear momentum. The upper bound of y_n is set because of $y_n = x_n < x_{n-1}$. The other bounds can be understood easily. These $2n-1$ fold integrations generate the $(2n-1)$ -th powers of logarithms. The non-ladder diagrams do not have this recursive structure and thus contain no LLs.

Evaluating the above integral leads to the result

$$\sigma_{\text{LL}}^{N^{n-1}\text{LO}} = -\frac{2\alpha^{n+1}}{(2\pi)^{n-2}s} \frac{1}{(n-1)!(n+1)!} \ln^{2n-1} \tau. \quad (12)$$

This formula agrees with the NLO and NNLO results in Eq. (7). To further validate the result, we calculated the NNNLO ladder diagram using the multiloop techniques described above, and found full agreement. The double factorials in the denominator lead to a strong numerical suppression at high orders, explaining why NNLO contributions are not so prominent for Compton scattering in the high-energy limit where large logarithmic enhancement exists.

Summing the all order corrections, we obtain the LLs resummed cross section

$$\sigma_{\text{LL}} = -\frac{8\pi^2\alpha}{s \ln \tau} I_2 \left(\sqrt{\frac{2\alpha}{\pi}} \ln \tau \right) = \frac{2^{9/4} \pi^{7/4} \alpha^{3/4}}{s(-\ln \tau)^{3/2} \tau \sqrt{2\alpha/\pi}} \quad \text{as } \tau \rightarrow 0, \quad (13)$$

with $I_2(z)$ being the modified Bessel function of the first kind. In the second line of the above equation, we present the asymptotic expansion of the resummed result in the limit of $\tau \rightarrow 0$. For fixed m , the cross section is scaling as $s^{-1+\sqrt{2\alpha/\pi}/\ln^{3/2}(s/m^2)}$ as $s \rightarrow \infty$, a pattern in contrast to the Regge trajectory. On the other hand, the cross section becomes divergent as $m \rightarrow 0$ for fixed s since new infrared divergences would emerge in this limit.

Comparison with data.— The strong suppression of LLs at higher orders ensures that our combined NNLO + resummation result provides an exceptionally precise prediction for the Compton scattering cross section. This

FIG. 3. Comparison of theory and experiment for Compton scattering. PrimEx [64] (4.400–5.475 GeV) and GlueX [65] (6.5–11.1 GeV) data for ^{12}C (magenta), ^{28}Si (blue), and ^9Be (orange) are compared to theoretical predictions at LO (green dashed) and NNLO+LL (black solid). The NLO result is not shown as it is visually identical to NNLO+LL.

is demonstrated phenomenologically in Fig. 3, where we compare our most precise theoretical prediction with high-precision data from the PrimEx [64] and GlueX [65] collaborations using photons with energies of 4.400–5.475 GeV and 6.5–11.1 GeV, respectively. The numerical values of the fine-structure constant and electron mass are taken from precise measurements of [66] and [67], i.e., $\alpha = 1/137.035999$ and $m_e = 0.509108$ MeV. The theory and data show excellent agreement. We emphasize that the combined NNLO and resummation effects are minuscule (at the 0.05% level) in this energy regime, underscoring the rapid convergence of the perturbative QED series and the definitive nature of our prediction.

Summary.— We have performed a precision study of the Compton scattering total cross section, resolving the long-standing puzzle of the size of high-order corrections, particularly the role of high-energy double logarithms. Our calculation, which provides the first complete NNLO result with full electron mass dependence, reveals that the anticipated double-logarithmic enhancement is indeed present but numerically suppressed due to a small coefficient, leading to excellent perturbative convergence.

We traced the origin of these logarithms to a specific kinematic configuration induced by a Glauber electron exchange. This insight allowed us to resum the leading logarithmic contributions to all orders in perturbation theory, yielding a compact result expressed in terms of a modified Bessel function. The all-order analysis uncovers a suppression mechanism: double factorial terms in the denominator systematically dampen the leading logarithms. The combination of our NNLO calculation and all-orders resummation delivers a precise QED prediction, which we have validated against recent high-precision data from the PrimEx and GlueX collaborations.

The methodology developed here—particularly the identification of Glauber-type exchanges as the source of leading logarithms—opens a new avenue for high-precision calculations in other fundamental processes. This approach is directly applicable to processes like $e^+e^- \rightarrow \gamma\gamma$ and $gg \rightarrow t\bar{t}$ in the high-energy limit, where similar logarithmic structures arise from massive fermion exchanges. Our work thus provides a blueprint for achieving percent-level precision in a range of scattering processes at future colliders.

Acknowledgments.— We would like to thank Jia-Yang Dong, Kirill Kudashkin, and Da-Jiang Zhang for the useful discussion and collaboration on similar projects. The work was supported in part by the National Natural Science Foundation of China (No.12325503, No.12321005, No.12275156, No.12005117) and the High-performance Computing Platform of Peking University. The diagrams are drawn using TikZ-Feynman [68].
